THE DIAGNOSIS OF EARLY CANCEROUS CHANGES IN PEPTIC ULCER

ARTHUR L. BLOOMFIELD, M.D.
SAN FRANCISCO

The discovery that an apparently benign gastric ulcer is in reality malignant is made often enough to justify the most strenuous efforts to avert such a tragedy. That this feeling is widespread at present is indicated by the abundant literature on the subject. Most of the papers, however, assert or imply that carelessness on the part of the physician is largely responsible and that something useful could be done if he did not stand idly by and allow the patient to drift into the late and hopeless stages of cancer. The thesis is sustained that careful study of people with ulcers which appear to be benign should make it possible to detect early malignant change and to effect a cure by prompt radical operation. It is my purpose in this paper to analyze this position and to see whether in fact it is a sound one.

I will consider first the data that are available for a so-called early diagnosis of carcinomatous gastric ulcer.

1 Roentgen examination. The most extreme suggestion which has been made is that every one over 40 years of age be subjected to half-yearly x-ray studies of the stomach to detect an early lesion. Now even supposing the impossible that people who feel well or who have minor digestive disturbances could actually be persuaded to follow such a plan, what sane radiologist would have the temerity to advise exploration on the strength of dubious x-ray appearances even if they roused considerable suspicion of trouble in his mind? For example, a man, aged 67, complained of a feeling of being full and uncomfortable after eating. These symptoms had been present for six months. He had lost 30 pounds (13.6 kg) and he felt weak. There was gastric anacidity. On x-ray study of the stomach Dr. Newell reported: "The pyloric zone is definitely increased to somewhat more than twice normal. Yet no ulcerative or nodular irregularity can be made out. I am, however, very apprehensive of an organic lesion at the pylorus." Six weeks later another examination showed no change and the patient has improved steadily over a period of five months. Furthermore, some films taken four years ago were compared with the present ones and the thickened appearance of the pyloric ring was already present then. It seems clear, therefore, that one was not dealing here with cancer and observations of this sort so commonly turn out to be of no con-

sequence that it would be unwarranted to subject patients to laparotomy on the strength of them.

2 The long and the short history. The statement is made that a long history of indigestion suggests a benign lesion whereas recent onset of symptoms is more common with malignant disease. There is doubtless some truth in this generalization, but there are so many exceptions that it will hardly serve as a working rule in practice. Especially in connection with the immediate problem of cancerous changes in peptic ulcer does such a rule break down. Many of the ulcer-cancer cases give long histories of indigestion, often with periods of freedom, and who can say when cancer supervened? Furthermore, cancer with a short history, indeed cancer at the very onset of symptoms is usually advanced from a surgical standpoint. Every one knows that the growth may attain great size before there is any definite departure from health.

3 Age and sex of the patient. Considerations of age and sex are unfortunately of little help in the present problem. It is precisely in cases of gastric ulcer that malignant change is likely to take place at a relatively early age, contrary to the general tendency for cancer to occur in older people. In the present series, which includes fifteen instances of probable or certain ulcer-cancer, three patients were under 35 years of age (26, 29, 33).

4 Size of the ulcer. The interesting measurements of Alvarez and McCarty¹ called attention to the generalization that large ulcers are more likely to be cancerous than small ones. There are, however, so many exceptions both ways that when one is confronted by the individual patient the following of such a dictum is unsafe. The most extreme example in my experience was that of a woman aged 33, with a long story (over ten years) of indigestion. Roentgenograms revealed an ulcer crater hardly more than 0.5 cm. in diameter and the gastric acidity was over 100. Here everything pointed to a benign lesion—age, sex, duration, acidity and size of ulcer. Yet within a year she was dead of inoperable cancer, verified by exploration and biopsy. The reverse that large ulcers may be clinically and histologically benign, must also be admitted.

5 Gastric secretion. The presence of a considerable amount of acid in the gastric secretion has quite rightly been regarded as evidence against primary cancer of the stomach. The relations in ulcer-cancer are less well understood and form the subject of the present inquiry.

In previous publications, Pollard and I² have presented the evidence for the view that anacidity, so

From the Department of Medicine, Stanford University Medical School.

Since the preparation of this paper, an article has appeared on gastric acidity and cancer of the stomach (Comfort, M. W. and Van Zant, F. R. *Am. J. Surg.* 26: 415 [Dec.] 1934) in which some of the conclusions reached by the author have been anticipated.

common in cases of cancer of the stomach is associated with a chronic gastritis antecedent to the growth and that it is not the result, as a rule, of destruction of the mucous membrane by cancer. In brief cancer tends to develop in stomachs already the seat of chronic gastritis with anacidity. There are however in any series of cases a certain number with normal or at least only slightly impaired gastric secretion, these it is difficult to reconcile with the thesis outlined and with them the present study is concerned.

TABLE 1—*Gastric Secretion in Ninety-Two Consecutive Cases of Cancer of the Stomach*

	Total	Per Cent
Total cases	92	
With anacidity	79	76
With free hydrochloric acid	--	24
Total males	72	
With anacidity	51	82
With free hydrochloric acid	11	18
Total female	20	
With anacidity	11	55
With free hydrochloric acid	9	45

In going over our records of the past few years it was possible to collect a consecutive series of ninety-two cases of cancer of the stomach in which standard histamine tests of gastric secretion had been done. The main statistical facts are shown in table 1.

The chart shows the distribution of the total acidity values of the twenty-two patients who secreted free hydrochloric acid as tested by Töpfer's reagent. While the number of cases is not sufficient to be conclusive it is of interest that they are not grouped at the anacidity end of the scale as one might expect but that they cover the entire range of normal secretion. In fact while there were only six cases with a total acid under 60 there were fifteen with acid of 60 or more. Such a tendency to a bimodal distribution curve suggests that one is dealing with two different classes of material; the obvious conclusion is that the cancers with acid may have a different origin from those arising on a basis of gastritis with anacidity.

It has been suggested that acid gastric secretion in the presence of cancer indicates that the growth has arisen on the basis of peptic ulcer. Our twenty-two cases of cancer with acid were carefully analyzed therefore, to see what evidence existed that such was the case, the conclusions being based on history, roentgen examinations and above all on autopsy or operative material. The data are summarized in table 2.

In nine of the twenty-two cases (table 4) it could definitely be said that benign ulcer preceded the cancer, and in six more this was highly probable. In five cases no conclusion could be reached and in only two was it certain that no ulcer had existed. There is strong evidence therefore that in most of this group of cases with preservation of gastric secretion peptic ulcer was the initial event. As a control, a series of twenty-two consecutive cases of cancer with anacidity were analyzed in the same way (table 3) and here the results were quite different. In not a single case was there proof of preceding ulcer and in all but four it was certain or probable that the cancer was not on a basis of ulcer. The entire situation is summarized in table 4.

The observations support the view that there are two types of cancer of the stomach which differ in their pathogenesis: (1) cancer arising in stomachs the seat of chronic gastritis with anacidity and (2) cancer arising in peptic ulcer. The former is the usual variety,

it comprises from two thirds to three fourths of the cases. Our statistics are also of some practical value, since they indicate that the presence of acid is the crucial factor in the diagnosis of cancer ex ulcere.

Finally there is the question as to whether a cancerous ulcer may really be malignant from the start—an ulcerated cancer. Everything seems against such a view; the fact that early cancers have been demonstrated histologically on the edge of a typical peptic ulcer and that in the anacidity group nothing suggestive of the craters of peptic ulcers is to be demonstrated. Indeed, the occurrence of cancer in a perfectly normal gastric mucosa must be an extremely rare event if it occurs at all.

In summary then evidence is presented that there are two types of cancer of the stomach of fundamentally different origin and that they may be differentiated with considerable certainty by the presence or absence of free acid in the gastric secretion. While this general idea is not a new one, the clearness of the concept has been obscured by the old erroneous view that cancer whether or not associated with ulcer, begins in a stomach which has a normal secretion and that in either case the secretion fails as the growth proceeds. On the contrary one variety of cancer arises in the stomach already the seat of gastritis and anacidity and the other, arising on the basis of ulcer, leads rarely if ever to any material change in the character of gastric secretion.

Finally it must be emphasized that here again studies of gastric secretion fail to help in the practical problem of deciding when a benign ulcer becomes cancerous since the acid persists unchanged or but little diminished. One cannot expect to find anacidity in these cases.

6 Symptomatic response to therapy. It is said that failure of ulcer symptoms to respond to therapy should rouse suspicions of malignancy. Such a rule is, however, of little practical value. In the present series of cancerous ulcers, for example, there was symptomatic relief in five cases for periods of from five to eight months before rapid decline set in. Conversely, it is common experience to observe patients with benign ulcer so refractory to medical therapy that eventually operation is done for this reason only.

Distribution of cases of cancer with acid according to degree of total acidity

The same may be said of decrease in size of the ulcer under medical therapy. Many benign ulcers fail to show any change in size by roentgen examination over long periods of time and in two of our malignant cases the ulcer seemed smaller at the very time when cancer was extending through the walls of the stomach. Technical difficulties such as lack of filling of the crater with the radiopaque mixture contribute to such errors.

In summary then, none of the criteria that have been proposed for the detection of early malignant change in peptic ulcer are reliable in the individual case, which is the practitioner's concern. The fact statistically valid that among ulcers large ones are more likely to be

malignant than small ones cannot be depended on to give the correct answer in the individual patient, and the same difficulty holds when one considers the type of history, response to therapy, age, sex, and the character of the gastric secretion. One is forced to the conclusion

at issue is whether or not all gastric ulcers should be resected as soon as recognized as a prophylactic against subsequent cancer. Now if partial gastric resection, which is indicated if anything at all is done were a trivial procedure no one would question the propriety

TABLE 2—Analysis of Twenty-Two Cases of Cancer of the Stomach with and without Reference to Antecedent Peptic Ulcer

Name	Sex	Age	Iled		History	Roentgen Examination	Course	Evidence Favors Ulcer
			Free	Total				
Ma	♀	37	14	40	Indigestion 1½ years worse past 2 months	Large ulcer high on lesser curvature	Died 1 year later autopsy report (done elsewhere) carcinoma of stomach	Yes
Ld	♂	40	26	40	Occasional indigestion for years for 6 months epigastric distress 12 hours p. e. relieved by food or soda	Appearance suggests large tumor encircling antrum no crater	Rapid decline operation inoperable cancer of stomach with metastases	?
Ar	♂	40	0	41	Stomach trouble 20 years	Irregular defect on greater curvature near pylorus no crater	Rapid decline operation inoperable cancer of stomach with metastases	?
Ho	♂	32	7	40	Stomach symptoms only two months	Pyloric obstruction	Subtotal gastric resection infiltrating cancer no ulcer	No
Ro	♀	44	26	2	Chronic gastric distress for many years worse recently	Constant niche on lesser curvature which has appearance of ulcer	Well on medical therapy for 6 months then rapid failure mass in epigastrium and iactatase x rays now show large irregular ulcer crater	Yes
Bees	♂	46	44	6	Stomach symptoms 1 year	Large ragged annular filling defect in antral region	Died 6 months later with metastases	?
Tris	♂	32	50	60	Epigastric pain for 2 years off and on	Large ulcer crater high on lesser curvature	Exploration in deep ulcer crater in indurated mass high on lesser curvature gastro-enterostomy 3 years later x rays show lesion more extensive patient very anemic and ill	Yes
McC	♀	46	44	60	Indigestion 2½ years	Ulcer crater on lesser curvature	Excision of ulcer 1 cm wide and 1 cm deep at one edge a few irregular glands with cells invading stroma died 2 years later autopsy recurrent carcinoma of stomach	Yes
Bo	♂	38	4	64	Stomach symptoms 4 months	Large ulcer (3.5 cm) high on lesser curvature	Three months later no healing of ulcer general condition rapidly worse	Yes
Fl	♂	40	52	68	Stomach symptoms off and on for 3 years worse past ten months	Widening of pyloric lumen space no crater	Pyloroplasty histologically cancer of pylorus (submucous) no ulcer died of recurrence	No
Mu	♀	44	20	76	Stomach symptoms 9 months	Large gastric ulcer (examined elsewhere)	Improved 5 months on medical treatment then rapidly worse operation extensive infiltrating lesion of lesser curvature with metastases inoperable	Yes
Ll	♀	37	23	76	Stomach symptoms intermittently for 4 years worse past 4 months	Huge defect on lesser curvature	Gastric resection huge ulcerated lesion (cancer) impossible to tell how it started	?
Vi	♀	26	70	78	Symptoms started 2 years ago exploration then large ulcer (not excised) seen high on lesser curvature	Crater 4 cm in diameter on lesser curvature	Improved on medical therapy for 3 months rapid failure then exploration inoperable cancer	Yes
Sn	♂	34	46	84	Indigestion 2 years worse past few months	Large filling defect involving antrum	Resection of stomach with removal of growth specimen shows ulcer crater 2 by 4 cm carcinoma was rising in base of ulcer and spreading through stomach wall	Yes
Co	♂	40	74	89	General failure for a year no definite gastric symptoms	Slight irregularity on lesser curvature	Autopsy on lesser curvature 9 cm from pylorus a shallow ulcer 2 by 4 cm one edge of this shows definite cancer histologically	Yes
Ur	♂	31	72	90	Indigestion 4 years much worse 3 weeks	Small ulcer crater near pylorus with obstruction	Subtotal gastrectomy ulcer 1.5 by 4 cm histologically cancer	Yes
De	♂	34	102	106	Epigastric pains 4 months	Ragged annular filling defect at pylorus with partial obstruction	Pyloric resection advanced ulcerated cancer impossible to tell about early stages	?
Ed	♂	38	50	108	Indigestion 4 months	Ulcer crater 2 cm in diameter on lesser curvature	Rapid failure metastases in lymph nodes and liver	Yes
Be	♀	29	68	110	Indigestion 2 years	Ulcer on lesser curvature near pylorus 1 cm in diameter	Temporary relief by medical therapy 4 months later increase of symptoms x rays showed ulcer larger operation cancer	Yes
Gr	♂	53	98	112	Stomach symptoms 2 months	Annular defect near pylorus with partial obstruction	Exploration annular cancer no ulcer made out	?
Ma	♀	32	106	114	Indigestion for 16 years relieved by alkali	Ulcer crater 1.5 cm in diameter on lesser curvature 1 month later crater smaller	Complete relief on medical therapy for 3 months then mild obstructive symptoms operation indurated area on lesser curvature with ulcer in center gastro-enterostomy only done died 1 year later autopsy cancer of stomach	Yes
F	♀	33	110	120	Indigestion 4 months previous periods of distress	Ulcer crater near lesser curvature 6.5 cm in diameter	Response to medical therapy for months size of ulcer by x rays unchanged then rapid failure exploration inoperable cancer (biopsy)	Yes

that it is impossible even after most careful study and observation to be sure whether early cancerous changes have taken place in an apparently benign peptic ulcer.

If, then, it should be admitted that such changes cannot be detected clinically with any useful degree of certainty, if, in brief, it is impossible to differentiate between benign and malignant ulcer until late and obvious evidences of cancer are present then the point

of a prophylactic operation just as no one hesitates to have a pigmented mole removed to avoid possible melanosis. Unfortunately the operation is a serious one with considerable immediate mortality, so that the situation will not be bettered unless the hazard of cancerous changes in ulcer is greater than the hazard of operation. It is necessary, therefore to evaluate the statistics in regard to these matters.

First as to the hazard of a benign ulcer becoming cancerous. The general feeling in the literature is that probably not more than 5 per cent of apparently benign peptic ulcers are in fact malignant; this is in accord with our own experience. Dr. Chang has recently studied the cases from this clinic. A consecutive series was collected in which the roentgen examination showed craters typical of simple gastric ulcer without other change. It was assumed that if after a follow up period of two years the patient was well the ulcer was benign

sistent indigestion and with the social and psychologic hazard that must be met when a serious operation is advised. Finally, operation does not necessarily save the patient from cancer, even if only the earliest malignant changes are present. This is well shown by the Mayo series¹ of resections for early cancer or cancerous ulcer. Among sixty-eight such cases in which malignancy could be demonstrated only by the microscope there were thirty-six deaths, or 52.7 per cent presumably of recurrences.

TABLE 3—Analysis of Twenty-Two Cases of Cancer of the Stomach with Anacidity with Reference to Antecedent Peptic Ulcer

Number	Sex	Age	History	Roentgen Examination	Course	Evidence Favors Ulcer
1	♂	74	Indigestion 5 months	Large filling defect at cardia	Metastases to liver and elsewhere	No
2	♂	64	Stomach symptoms 6 months	Ragged irregularly at cardia		No
3	♀	73	Vague failure of health 6 months	Deformity of entire lower half of stomach; no crater	Patient almost moribund	No
4	♀	53	Vomiting one week	Whole antral portion cut off leaving only irregular funnel shaped hollow with almost complete obstruction		No
5	♂	61	General failure 5 months; no gastric symptoms	Distal two thirds of stomach completely obliterated by a ragged lesion	Autopsy: large cancer of lesser curvature of stomach in distal third; no sign of ulcer	No
6	♂	57	Stomach trouble for years; worse past 4 months	Huge irregular filling defect at antrum; no crater	Resection of lesion; advanced sloughing growth	No
7	♂	40	General failure 7 months; no stomach symptoms	Huge ragged lesion of antrum with palpable epigastric mass	Patient moribund	No
8	♂	54	Vomiting 2½ months	Huge irregular defect on greater curvature	Metastases in liver	No
9	♀	26	Indigestion onset 3 years ago	Irregular filling defect at antrum involving both greater and lesser curvatures	Operation: a hard nodular mass extending from pylorus for 8 cm; biopsy showed cancer	?
10	♂	41	Epigastric pain 3 weeks	Large filling defect in mid portion of stomach	Exploration: hard nodular mass near cardia; metastases to liver	No
11	♂	72	Epigastric distress 8 weeks	Irregular filling defect of greater curvature in its middle third	Autopsy: entire stomach except 10 cm at cardia thickly infiltrated with tumor; no localized ulcer	No
12	♂	40	Heavy feeling in stomach for 3 weeks	First x-ray of stomach did not show disease; 5 months later tubular defect in body of stomach; ragged on greater curvature side		No
13	♀	70	Abdominal distress 2 months	Large ragged defect near cardia on greater curvature; no crater	Rapid downhill course	No
14	♂	37	Epigastric distress 3 months	Pyloric obstruction	Operation: resection of pyloric cancer; no ulceration	No
15	♀	40	Digestive symptoms 2 months	Irregular filling defect of entire pyloric antrum; no crater	Operation: unresectable cancer near pylorus with metastases; no signs of ulcer	No
16	♂	60	Epigastric pain 6 months	Irregular filling defect of antrum mainly on greater curvature; no crater seen	Biopsy of skin nodule: adenocarcinoma	No
17	♂	70	General failure and loss of appetite for 3 months	Large filling defect at cardia	Multiple metastases	No
18	♂	47	Indigestion 4 years; abdominal pain 6 weeks	Constant defect in antral region	Operation: resection of pyloric cancer; huge shallow superficial ulceration of mass which shows cancer everywhere	?
19	♂	54	Epigastric pain 3 months	Large filling defect at antrum	Operation: resection of pyloric cancer; no ulcer	No
20	♂	33	Vomiting for a year	Ragged defect at antrum with partial obstruction; no crater	Metastases	No
21	♀	51	Epigastric distress and vomiting 4 weeks	Sawed off pylorus	Operation: huge cancer at pylorus (biopsy)	?
22	♀	60	General failure 5 months; no special stomach symptoms	Huge irregular defect involving half the stomach	Operation: huge cancer; biopsy inoperable	?

at the time of the first examination. Sixty-two cases were studied in this way. Two of the patients, or 3.2 per cent, turned out definitely to have cancer, and in a third case there was serious suspicion of cancer without verification. At most, then, three or 4.8 per cent, of the series of apparently benign ulcers were, or soon became cancerous. These figures do not tell of course how many ulcers would have become cancerous if observed over a longer period—say ten or twenty years—and from this standpoint the figure of 5 per cent would doubtless have to be increased to some extent. Gastric resection, however, involves an operative mortality of at least 10 per cent even in skilled hands³ and this figure could safely be doubled if one includes operations done by surgeons in general. In addition, even if resection is accomplished, one still has to reckon with possible recurrence of ulcer, with postoperative complications such as adhesions, obstructions and per-

SUMMARY

One arrives therefore at certain definite conclusions. First, it is impossible by clinical observation to determine early cancerous changes in apparently benign

TABLE 4—Evidence of Antecedent Gastric Ulcer in Cases of Cancer of Stomach with Anacidity and with Preservation of Gastric Secretion

peptic ulcer. The various criteria while statistically valid, are subject to so much variation that they cannot be depended on in the individual case even though great

³ Rienhoff, W. F. and Baker, B. M., Jr. The Medical and Surgical Aspects of Peptic Ulcer. Internat. Clin. 2: 167 (June) 1934.

size of the lesion points strongly to cancer. Hence, if prophylactic surgery is to be used, one should consider every gastric ulcer as malignant *in posse* if not *in esse* and one should excise them all. But the surgical risks of such wholesale gastric resection are distinctly greater than the hazard of ulcer being or becoming malignant.

The only practical attitude to adopt, therefore, is to regard small apparently innocent gastric ulcers as in fact benign until evidence to the contrary is weighty enough to arouse serious suspicions and to accept the fact that a certain number of unavoidable tragedies will occur. They will occur in the future as they have in the past, not necessarily because physicians are careless but because they are helpless in the face of an insoluble problem of diagnosis.

CARCINOMA OF THE RECTUM

SOME CAUSES FOR THE POOR PROGNOSIS

J. ARNOLD BARGEN, MD

AND

EUGENE T. LEDDY, MD

ROCHESTER, MINN.

Carcinoma of the rectum is a very serious disease although it may be uncommon in the experience of any individual physician its early recognition is essential to the life of the patient. Many patients who have carcinoma of the rectum appear at the Mayo Clinic and elsewhere for examination when the local lesion is hopelessly inoperable. This also implies that many of these lesions are beyond even palliative irradiation when first seen. Rankin, in a review of 1727 cases of malignant disease of the rectum that were observed at the clinic discovered that only 55 per cent of the lesions were operable and that resection was possible in only 35 per cent. This indicates obviously that in any group of rectal carcinomas the expectancy of life for the patient is short. When it is recalled that carcinoma of the rectum causes definite and annoying symptoms, such as rectal bleeding, pain, constipation and diarrhea which get progressively worse and that about 95 per cent of all these lesions are within reach of the examining finger, these facts are disheartening.

We realize that carcinomas of the rectum are not alone in not being treated at their most favorable stage. However, after following many patients who have had carcinoma of the rectum, from the time of their admission to the clinic until they were entirely relieved of their trouble or until their demise, we have come to be of the opinion that postponement of care and procrastination are more prevalent among these patients than they are among those who have most other types of carcinoma. The questions that obviously arise are: Why should this be so? Are the methods of diagnosing carcinoma of the rectum at fault? Are physicians more likely to be indifferent to lesions in this part of the body than to lesions in other parts? Does the ubiquitous advertising of cures for piles and constipation hinder the early diagnosis of carcinoma of the rectum because the patient treats himself?

Our observation of so many advanced cases of this disease prompted us to make a review of the causes of late diagnosis. Each of us interviewed 100 patients who had carcinoma of the rectum, as they came under

our personal observation. One of us (J. A. B.) questioned those who were admitted to the intestinal service for preoperative preparation. These were patients who were to be subjected to radical operation or who were about to undergo colostomy for relief of obstruction that was the result of an advanced lesion. The latter patients were placed in the hospital for temporary comfort. The other of us (E. T. L.) questioned 100 patients who were sent for palliative irradiation or who were thought suitable for primary therapeutic irradiation. Both of us followed the same outline for questioning. In addition to the usual points that are covered in an intestinal history the following list of questions was asked every patient and the answers were verified when necessary by an interview with a relative of the patient.

What were the first symptoms which you noted?

What was the progress of the disease?

What did you think was wrong with you?

Did you attempt to treat yourself?

How long had the symptoms been present before you consulted a physician? If there was a delay why?

What kind of an examination did the physician make and what treatment did he prescribe?

Ninety-two of the 200 patients had consulted a physician within a month from the onset of symptoms. The other 108 had not consulted a physician until from two to twenty-four months after the onset of their trouble and until their own treatment had failed. Granting that a tumor must progress to a certain stage before it can produce symptoms, it seems obvious that in these 108 cases the malignant condition must have progressed to a less favorable stage during the time these patients were treating themselves. It was among this group of patients that adequate treatment usually could not be employed because of the advanced condition of the disease. Only two patients both of whom had severe symptoms came directly to the clinic before they had consulted any physician.

The American Society for the Control of Cancer, and most authors who have written on the subject regard one month as an average amount of time during which a patient may have symptoms before a correct diagnosis is made and treatment instituted. We also believe that a correct diagnosis should be made within one month after the symptoms are present. It might be said in passing that we do not regard the specific mention of carcinoma as indicating correct diagnosis because indirect but equally reliable information about the diagnosis can be obtained from what the physician told the relatives of the patient and from the treatment. As there are but two methods of treatment that are accepted generally—irradiation and operation, we have regarded the use of any medical treatment as an indication of wrong diagnosis, provided we could exclude deliberate experimentation on the part of the physician, or quackery.

In this group of 200 cases, the earliest symptom was bleeding, pain occurred next, then constipation and finally, diarrhea. Most patients complained of combinations of these and said that their symptoms had been getting worse, yet these symptoms, as annoying as they were, did not bring these patients to their physicians early. Self medication had been the rule among these patients, this had included the regulation of diet, the notorious remedies for constipation, and the equally famous "pile cures." In this connection it is necessary to refer only to the remedies for regulation of the

bowels, which are advertised by radio, on billboards in newspapers and in magazines. It seems too bad that the excellent work being carried out by the American Society for the Control of Cancer should be minimized by advertising to a gullible public, and that patients should treat themselves without consulting a physician.

We tried to discover, by questioning the patient why the first physician who had been consulted had failed to make a rectal examination in so many instances and learned that there had been several reasons for this. Often the patient had objected to such an examination and the physician in an attempt to make the best of an unsatisfactory situation, had prescribed a palliative and had requested the patient to return shortly, or else the physician had hesitated to add to the pain of an extremely uncomfortable individual by making a rectal examination and had therefore prescribed palliative medication. It was disclosed that there were three reasons for the failure of these patients to return to their physicians as instructed: first they had obtained relief and had decided that it was unnecessary to return; second, they had discussed their symptoms with friends and had tried the remedies that their friends had recommended; or third, they had feared that they might have carcinoma and because of the relief that had resulted from medication they had decided that they did not have carcinoma but that they had only the symptoms of it. Meanwhile the carcinoma had progressed in silence. The time invariably had come when the patients had had intolerable symptoms and when the remedy no longer had given relief. At this time they had returned to their physicians or had consulted others who had had little trouble in recognizing the underlying cause of the symptoms. Valuable time had been lost in this period by the treatment which had masked the symptoms of carcinoma. Too often the condition had been diagnosed wrongly as 'hemorrhoids' or 'colitis' without a proctoscopic or roentgenologic investigation, and hemorrhoidectomy or other palliative measures had reduced the chances of much greater benefit from correct radical treatment.

Another reason for delay in starting correct treatment had been the fact that both patient and physician often had felt that the operation for carcinoma of the rectum was too formidable. It should be remembered, however, that advances have been made in the management of these cases in recent years which have helped to make surgical treatment of carcinoma of the rectum very satisfactory. In the hands of expert and experienced operators who have their patients prepared by improved methods of preoperative treatment, radical operation entails a mortality of less than 5 per cent. The preoperative vaccination against peritonitis, the thorough emptying of the colon, the replenishing of a depleted water balance, the forced storage of carbohydrates, and the isolating of patients who have disorders of the colon as a unit under combined medical and surgical care are measures that have tended to increase the safety of rectal surgery. Surgical opinion throughout the world is unanimous that the earlier the patient comes for treatment the greater is the likelihood of cure by operation, whereas the later the diagnosis is established the less is the chance of cure by any treatment.

When patients finally have had the diagnosis of carcinoma of the rectum established, much tact in the discussion of the necessary treatment is indicated. Patients do not like to have a colonic stoma if it can be avoided, and this can be done in certain favorable cases by

employing radiotherapy or segmental resection. Hence the fear that a patient has of the inconvenience of a colonic stoma may be groundless. Then, too, a colonic stoma, if suitably made, offers little inconvenience if the patient has been educated to care for it properly. W. J. Mayo has aptly illustrated an unsatisfactory colostomy by the story of the man who pulled the wheelbarrow of refuse. He did not push it because he hated the sight of it. But, as we have said, colonic stomas will cause little trouble if patients are given detailed instructions about their care. We have seen many patients who had refused to submit to colostomy and resection when these operations first had been recommended by their physicians and who later had consented to undergo the same operations on the advice of another physician who had allayed completely their fears of the undesirability of such procedures.

Finally in the minds of many there still seems to lurk the dread and hopelessness in regard to neoplasms of the rectum. This idea must be carefully expelled and the mind of the sufferer must be disabused. We never have found it difficult to convince a patient who had such a lesion that our present method of treatment was essential and satisfactory. It is fortunate that some carcinomas of the large intestine are notoriously slow in their growth and generally have a favorable prognosis. The exact status of a given lesion can be determined only by operation. These facts do not detract from the importance of an early diagnosis, for the nearer a carcinoma approaches operability the better is the chance of permanent cure by whatever method is indicated, radical extirpation or radiotherapy. It should be remembered that, in cases in which the patients are seen early and are carefully selected, radiotherapy without operation is a safe and dependable method of treatment.

This group of 200 cases demonstrates that inoperable carcinomas of the rectum occur largely because patients treat their own disease under the impression that their symptoms are common to most people and are not serious. Both patient and physician make a great mistake in gambling that a lesion is benign. It must be remembered that symptoms of carcinoma of the rectum simulate those of other benign lesions and even those of functional conditions. The importance of early correct diagnosis cannot be overemphasized from the prognostic point of view. Temporization and mismanagement cannot be too strongly condemned, for they will place many patients beyond all hope of cure and relegate them to palliation and hopelessness. If doubt exists about any given lesion or group of symptoms, the lesion should be considered carcinoma until it is proved otherwise by competent examination. The fallacy that rectal symptoms should be considered and treated as functional upsets is perpetuated unfortunately by the exploiters of nostrums and the physician is forced to compete with those who offer free medical advice for pecuniary reasons only. The patient, who lacks discriminating sense therefore treats his symptoms but not the underlying lesion until he becomes convinced, by his own failure to relieve himself, that medical advice is highly desirable. The patient who has rectal (or other) carcinoma and who by his own ignorance and neglect experiences the normal fatal outcome has a gloomy outlook to face. As he nears the end of his torture and learns that he might have been cured by relatively simple measures and that he has been deluded by false hopes through the treacherous

theories of dishonest prophets until his case is hopeless and his family is penniless, his lot is indeed pathetic. As carcinoma of the rectum can nearly always be diagnosed with the index finger, it is lamentable that so many patients who are afflicted with this condition do not consult a physician until it is too late to secure the greatest benefit.

CONCLUSIONS

A careful analysis of the answers obtained from 200 patients has led us to conclude that the poor prognosis of carcinoma of the rectum is the result of the following causes:

- 1 The frequent wasting of valuable time on the part of patients by self diagnosis and self treatment and by regarding the symptoms as unimportant

- 2 Delay by the physician to make a digital examination of the rectum

- 3 Lack of knowledge, on the part of the patient concerning the safety and satisfactory end results of rectal surgery

THE TREATMENT OF DIABETES WITH INSULIN (AFTER TEN YEARS)

CONTRASTING THE EFFECTS OF NORMAL AND OF THE OLDER DIABETIC DIETS

H RAWLE GEYELIN, M.D.

NEW YORK

During October 1923 I first attempted the administration of high carbohydrate diets to diabetic patients treated with insulin. Most of the diets employed at that time were not as high in their carbohydrate content, however, as the diets that I have used during the past nine years. A preliminary report of my earlier observations with the high carbohydrate or normal type of diet was made before the Section on Pediatrics of the Medical Society of the State of Pennsylvania in October 1925.¹ In January 1926 Sansum² reported the use of somewhat similar diets in a group of insulin treated diabetic patients. Adlersberg and Porges³ in 1927 also advocated high carbohydrate—"fat poor diets" for the treatment of diabetic patients receiving insulin. At that time it was agreed by all the investigators mentioned that these high carbohydrate diets increased the relative effectiveness of insulin in a majority of the cases studied. Many other clinicians, both in this country and in Europe, have subsequently adopted this method of treating diabetes, reporting similar satisfactory results.

Adlersberg and Porges,³ Rabinowitch⁴ and I¹ have all called attention to the importance of maintaining a

low fat content in these diets. The increased effectiveness of insulin that so commonly follows the substitution of the high carbohydrate-low fat regimen for the low carbohydrate-high fat regimen seems to be chiefly dependent on the degree to which fat is curtailed.

The amount of carbohydrate and its relation to the protein, fat and total calories in the various diets used by different observers in the past eight years has varied considerably. As a rule, however, the objective of most clinicians employing these high carbohydrate diets has been to make them approximately equal to the diets of normal people of similar age, sex, weight and physical activity.

The reasoning that originally led me to experiment with and eventually adopt the higher carbohydrate diet was as follows. Conceding that diabetes was due to an insulin deficiency and that the failure to metabolize food without glycosuria was directly proportional to this deficiency, the artificial administration of insulin in amounts sufficient to restore the total available body insulin to normal should result in the ability of that individual to metabolize a normal diet ("normal" both as to quantity and quality of food).

It is axiomatic that the facts concerning any new therapeutic procedure can be determined only when the application of such procedure has been tested in many cases over a period of years. I have therefore chosen this occasion, ten years after diets high in carbohydrate were first administered, to summarize briefly the results of treatment as I have observed them in a group of 150 cases of diabetes treated with insulin and a high carbohydrate diet during the past ten years. Of this group, twenty-eight have been under observation for from eight to ten years, seventy-eight have been under observation for from five to eight years, and the remainder, or forty-four, have been under continuous observation for from one to five years. This group of 150 patients is only a fraction of the total number of more than 900 cases of diabetes treated with insulin during the past twelve years. The basis of selecting this group of 150 insulin treated patients has been

- 1 Length and continuity of treatment
- 2 Reliability and completeness of their records
- 3 Relative freedom from complicating conditions
- 4 Extensiveness of laboratory data

Limitation of space prevents the presentation of complete protocols of the entire group. I have therefore selected the records of ten patients for tabulation because this group is representative of the variation of the results obtained in the larger group. The group of ten has been further subdivided into two groups of five patients each. In the first group, patients 1, 2, 3, 4 and 5, are included those who have been continuously under my care for from eight to fifteen years. Patients 1, 2, 3 and 4 started insulin treatment from ten to eleven years ago. The second group, comprising patients 6, 7, 8, 9 and 10, had all been under the care of other clinicians for periods ranging from one to nine years. They had all received the lower carbohydrate-higher fat types of diet and had been treated with insulin for at least a year previous to coming under my care. In this respect they serve as a control group.^{4a}

It is necessary at this point to explain the method I have used in compiling the tables and charts from the data in the records. In each of the fifteen tables, the total number of units of insulin, the total grams of

Read before the Section on Miscellaneous Topics, Session on Nutrition, at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

Because of lack of space, this article is abbreviated in THE JOURNAL. The complete article appears in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped addressed envelope.

^{4a} The cases referred to do not all appear in the article as printed in THE JOURNAL but can be found in the reprint.

carbohydrate, protein and fat and the total calories and available carbohydrate have been averaged for the year in terms of the daily quantities of each. The weight and height columns in each chart are designed to show the range of variation in early periods or, as in another group of tables, averaged over a period of years. The figure in the column of the tables listed as "Grams Carbohydrate per Unit of Insulin" is, of course, also a yearly average on a per day basis. This figure is obtained by dividing the average daily total grams of available carbohydrate by the total daily dose of insulin. This may be described as the ratio of insulin to carbohydrate or the number of grams of carbohydrate that each unit of insulin will oxidize. It is the best method that I have been able to devise for the estimation of

dextrose. The columns in the tables showing the figures for blood sugar and blood cholesterol are expressed in terms of milligrams per hundred cubic centimeters of blood and unless otherwise indicated, represent the range of blood sugar and cholesterol during the periods indicated. In the charts appended for cases 2, 3 and 4 the blood sugar and blood cholesterol readings are given as the individual determination.

PROTOCOLS

CASE 2—Reeve A. born Aug 27, 1915 admitted May 2, 1919, in whom the onset of diabetes was manifested by symptoms in February 1919 and proved by urinalysis in March, was treated by diet alone from the time he was first seen until Sept 12, 1922, at which time insulin treatment was begun. His maximum tolerance for food before insulin was begun was below 10 Gm

TABLE 3—High Carbohydrate-Low Fat Diet in Case 2 (Reeve A, Male)

insulin effectiveness. It may be objected that this method of calculating the effectiveness of insulin is incorrect because it does not include the measurement of that quota of insulin available from the patient's pancreas. This contention is obviously correct, but as there is no means of estimating the influence of the native insulin, I am forced to limit my measurement of the effectiveness of insulin to that quota which is parenterally administered. In children and in other

of carbohydrate, 30 Gm of protein and 80 Gm of fat. On this diet, while in the hospital eight days before insulin was started, the urinary dextrose averaged 34.3 Gm a day.

The subsequent course of the diabetes is summarized in tables 3 and 4. During 1932-1933 and the first three months of 1934 the patient suffered from an extremely severe pansinusitis, which necessitated two radical operations, one on the maxillary sinus and one involving the frontal sinus. Also in 1932 he suffered a compound fracture of both bones in his right arm. Coincidentally with these occurrences it required considerably

* A dietitian has always lived with this patient and the averages are computed from daily charts kept throughout the patient's course of treatment. The patient's weight of January 1931 was 127½ pounds and her height was 5 feet 0¼ inches.

† Preinsulin period of forty-six consecutive days.

‡ Insulin was begun Sept 1, 1922. Average for 122 days (from Sept 1, 1922 to Jan 1, 1923).

§ Average for 383 days (2 days in September were omitted in keeping the chart).

cases of maximum severity, the amount of insulin secreted by the pancreas is surely minimal and reasonably constant. The amount of insulin secreted from the pancreas in the milder forms of diabetes probably varies considerably from day to day and even from month to month, but this variation is greatly minimized when expressed in terms of yearly averages. For the comparative purpose for which I have used it, I believe that this method of estimating the effectiveness of insulin is adequate and at least gives an accurate comparative measure of the action of the parenterally administered insulin in its effect on the oxidation of

more insulin to keep him sugar free. At the present time he is going to public school, is leading an athletic life and works in extra hours to help support his family.

CASE 3—A B, a girl, born March 4, 1914, admitted April 2, 1921, in whom the onset of diabetes occurred in January 1921 with polyuria, polydipsia and loss of weight, glycosuria being discovered in the early part of March, weighed 42 pounds (19 Kg) and ranged between 40 and 42 pounds until the time that insulin was first given Aug 30, 1922. Before insulin was given her maximum food tolerance was 15 Gm of carbohydrate, 45 Gm of protein and 85 Gm of fat.

The subsequent course in this case can be observed in tables 5 and 6. At the present time she is healthy and vigorous and is leading an outdoor life with considerable exercise and is in

excellent physical condition. The menses were established at the age of 14 years.

The patient's early record is more completely set forth by Geyelin and his associates.⁵

CASE 4—Edwin J. M. born April 29, 1912, admitted Nov. 4, 1922, in whom the onset of diabetes first was manifested by symptoms, Feb. 22, 1918, and proved by urinalysis in March 1918 and Nov. 20, 1922. He lost weight steadily from a maximum of 38 pounds (17.2 kg.) at the age of 6 to 27 pounds (12.2 kg.) (with edema) on Nov. 20, 1922 (four and one half years later), at which time insulin was begun. In a control period of three days before insulin was started on a diet of 20 Gm. of carbohydrate, 35 Gm. of protein and 45 Gm. of fat averaging 603 calories, the daily excretion of sugar averaged 41.1 Gm. and the daily nitrogen loss was 3.3 Gm.

The course of the diabetes under insulin treatment can be seen in tables 7 and 8. At the present time the boy is engaged in vigorous physical exercise and, aside from transitory infections of the upper respiratory tract, he has enjoyed excellent health during the past eight years.

CASE 5—Martha Jean C. born May 3, 1922, admitted June 30, 1927, in whom the onset of diabetes occurred Aug. 1, 1925.

Amounts of sugar infrequently has remained sugar free ever since. At the time of his first visit he showed marked pitting edema and weighed 118 pounds (53.5 kg.). He lost 10 pounds (4.5 kg.) during the first six weeks and has since regained his weight without edema, so that at the present time his weight is 135 pounds (61.2 kg.).

CASE 7—Herbert N. born March 1, 1914, admitted June 4, 1932, showed manifestations of the onset of diabetes in January 1930. He was desugarized by starvation and kept sugar free on a low diet (exact figure not known) until October 1930, at which time he was given insulin and, until admission, was kept on a diet of 80 Gm. of carbohydrate, 90 Gm. of protein and 215 Gm. of fat. Glycosuria had been combated by insulin which averaged 110 units a day from October 1930 until June 4, 1932. During this period the patient had suffered from many hypoglycemic reactions some of which had been very severe. His chief complaint when he was first seen, was that he was hungry all the time.

Since admission the course of the patient's diabetes is summarized in table 12. The total amount of insulin required daily to maintain an aglycosuria has varied from 70 to 52 units a day and he feels much better as regards physical endurance and mental attitude and is now satisfied with his diet.

TABLE 7—High Carbohydrate Low Fat Diet in Case 4 (Edwin J. M.)*

Year	Diet				Total Dextrose	Insulin	Grams of Carbohydrate per Unit of Insulin	Urine Sugar	Range of Blood Sugar per Cent	Range of Blood Cholesterol per Cent	Range of Weight Pounds	Range of Height

* Averages for 170 consecutive days (from beginning of treatment to end of 1927).

was desugarized without insulin and kept sugar free on diet alone until Dec. 1, 1925. At this time insulin was started and continued under the care of her local physician until the time of admission. Diet during that interval was 50 Gm. of carbohydrate, 51 Gm. of protein, 85 Gm. of fat and her insulin dosage was 32 units a day. On this diet and insulin dosage she remained sugar free but had gained only 6 pounds (2.7 kg.) during the eighteen months period.

Diet and insulin were changed as indicated and her course under treatment has continued as shown in tables 9 and 10.

CASE 6—Harold G., born Jan. 24, 1914, admitted Feb. 24, 1932, in whom the onset of diabetes occurred suddenly in February 1923 with the usual symptoms, almost went into coma. He was treated with insulin from the outset the total amount ranging from 40 to 75 units a day. The average amount over the period of nine years was 60 units a day. His diet had varied from 50 to 100 Gm. of carbohydrate from 60 to 100 Gm. of protein and was over 200 Gm. of fat. At the time of his first visit he was showing considerable glycosuria, 4.2 per cent the blood sugar was 241 mg. per hundred cubic centimeters of blood and blood cholesterol 389 mg.

The subsequent course of events is shown in table 11. He was first put on a diet of 300 Gm. of carbohydrate, 85 Gm. of protein and 75 Gm. of fat with 60 units of insulin a day. He became sugar free within two months and except for moderate

CASE 9—Sylvia L. S., born Aug. 14, 1875, admitted Nov. 9, 1933, had lost 35 pounds (16 kg.) from the date of onset of diabetes January 1926, until April 1926. She was desugarized with a low diet and remained sugar free but continued to get weaker and was finally placed on a diet of 130 Gm. of carbohydrate, 65 Gm. of protein and 150 Gm. of fat with 32 units of insulin daily. On this diet she had gained approximately 22 pounds (10 kg.) and said she had remained nearly sugar free but had not been strong and had had a series of boils ever since 1929. Her diet at the time of admission and her insulin dosage were the same as just given. Her blood sugar was 176 mg. per hundred cubic centimeters of blood and her blood cholesterol was 285 mg.

She was immediately put on a diet of 275 Gm. of carbohydrate, 85 Gm. of protein and 85 Gm. of fat with 32 units of insulin a day. This dosage had to be increased to 40 units a day before she was desugarized. She has remained sugar free on this dose. Blood sugar, May 29, 1934, was 105 mg. per hundred cubic centimeters of blood and blood cholesterol was 250 mg. It is interesting to observe that in this patient the blood cholesterol, although it has remained below 220 mg. per hundred cubic centimeters of blood in six determinations from Dec. 4, 1933, until April 27, 1934, has now increased to 250 mg. Concomitantly with this increase in blood cholesterol, the patient admits that she has been overeating the fat content of her diet.

CASE 10—William I., born Sept. 21, 1910, admitted April 5, 1933, has had diabetes for one year. The onset, in April 1932, was sudden. He was immediately put on a diet of 100 Gm. of

⁵ Geyelin, H. R., Harrop, George, Murray, Marjorie F. and Corwin, Eugenia. The Use of Insulin in Juvenile Diabetes. *J. Metab. Research* 2 (Nov. Dec.) 1922. This case is listed as case 2 and cases 2 and 4 in the present paper are listed in Harrop's paper as cases 3 and 7 respectively.

carbohydrate, 50 Gm of protein and 50 Gm of fat. He was desugarized for four days with insulin. He had no more insulin until August, and at that time the diet was gradually increased to 150 Gm of carbohydrate, 120 Gm of protein and 180 Gm of fat, with 65 units of insulin a day. He has been on this diet ever since and has remained sugar free. The insulin dosage is still 65 units a day. The blood sugar at this time was 125 mg per hundred cubic centimeters of blood and blood cholesterol was 368 mg.

On admission the patient was immediately put on 350 Gm of carbohydrate, 120 Gm of protein and 90 Gm of fat, and it was possible to keep him sugar free on a dose of 52 units daily within three weeks of the time the diet was changed. From

hydrate. Of the total number of 150 cases, in thirty-nine cases, or 26 per cent, I have been able to increase the carbohydrate intake of the diet from 100 to 200 per cent or more without requiring additional insulin (cases 1, 6, 7 and 10). Some of these cases have required even less insulin on the higher carbohydrate diets than they had required on the lower carbohydrate diets (table 12). Sixty-nine of my patients, or 46 per cent of the 150 cases studied, have required less than a 20 per cent increase in insulin when transferred from low to high carbohydrate diets. In this group the change of diets has often involved an increase in carbo-

June 1, 1933, until June 1, 1934, the patient has remained on this diet and has averaged 46 units of insulin daily and the urine has remained sugar free. The most recent blood sugar, done in January 1934, was 125 mg per hundred cubic centimeters of blood, and blood cholesterol 142 mg. The patient writes that he has gained several pounds, and that he has considerably more physical endurance than he had on the previous lower carbohydrate higher fat diet.

COMMENT

From the tables and charts it will be observed that the effectiveness of each unit of insulin per gram of carbohydrate, i. e., insulin effectiveness, increases as the carbohydrate is increased and the fat in the diet is

hydrate which amounted to more than 300 or 400 per cent.

In forty-two cases, or 28 per cent of the total number of cases, the increase of insulin required after the change from a low to a high carbohydrate diet amounted to an increase in insulin of from 20 to 50 per cent, but rarely more than this. In many of these cases such increases in insulin have been temporary, and after the lapse of a year or more it has been possible to decrease the insulin. There are a few patients, however, who show a steadily increasing need for insulin in spite of the continuation of high carbohydrate diets, but these instances are usually cases in which no attempt

decreased. Generally speaking, this increased effectiveness of insulin is more striking when the carbohydrate of the diet has reached a certain maximal amount, apparently specific for a given individual. This increase of insulin effectiveness is, I believe, maximal when the relation of carbohydrate to fat in the diet is 3 or 4 Gm of carbohydrate to 1 Gm of fat. Not only in this group of ten patients, but also in the remaining 140 cases studied, I have noted that in most patients, after a transfer from diets low in carbohydrate to diets maximally high, the effectiveness of insulin is not fully attained until a certain lower level of fat is achieved. As an instance of this, I shall cite case 2, in which in 1926 after the fat had been lowered 20 Gm, the effectiveness of insulin was increased from 3.9 Gm of carbohydrate per unit of insulin to 6.6.

From the protocols and tables presented, it will also be observed that the absolute amount of insulin required to oxidize increasing amounts of carbohydrate is often augmented but the increase of insulin is in most instances not proportional to the increase of carbo-

has been made to bring about extreme reduction of fat. It is also possible that the effect of low grade chronic infections, such as sinusitis, and the breaking of diet, particularly the overeating of fat, is responsible for the increasing need for insulin. As an example of the temporary need for increased insulin after the patient has been transferred from a low to a high carbohydrate diet, I may cite case 3. This patient in January 1925, on a diet of 80 Gm of carbohydrate, 63 Gm of protein and 97 Gm of fat, averaging 1,441 calories required 47 units of insulin to keep glycosuria at a level of 15 Gm daily. The diet was changed to 200 Gm of carbohydrate, 70 Gm of protein and 85 Gm of fat in April and during this month and the following month the patient required 81 units of insulin daily to maintain a sugar-free urine. After this, the total insulin needs slowly decreased until in October, November and December she required only 46 units a day to keep the urine sugar free on a diet of 255 Gm of carbohydrate, 70 Gm of protein and 65 Gm of fat. The insulin to carbohydrate ratio or dextrose equivalent of insulin had

rised from 23 in January 1925 to 76 in December 1925. Every urine voiding was tested for sugar daily throughout the year.

One of the objections that has been made to the use of the high carbohydrate diet as I have employed it is that it is a diet which of necessity, provides for normal nutrition and, in some instances, overnutrition. This is, of course, contrary to one of the oldest traditions of diabetic treatment. Undernutrition has for many years been advocated as a method of treatment for diabetes. In fact, by some it has been regarded as one of the fundamental principles of treatment. The assumption that undernutrition was the fundamental principle of diabetic treatment became widespread subsequent to 1914 owing largely to its advocacy by F. M. Allen. Allen and many of his adherents insisted that tolerance for carbohydrate (and also total food tolerance) could be increased by the persistent maintenance of undernutrition in any case of diabetes. The increases of tolerance that followed starvation and subcaloric diets were and still are readily obtainable in any form of diabetes, particularly the milder forms of the disease. In children, however, these increases following undernutrition are comparatively transitory in nature and are invariably followed by a steadily decreasing tolerance.

In children I have noticed that a certain moderate degree of overnutrition is occasionally unavoidable and in most instances is corrected within a year or two without the necessity of curtailing the diet. It is doubtful whether overnutrition or obesity in this group of cases has any permanent harmful effect on the diabetes. Overnutrition is particularly common in girls at the time of puberty. Attempts to correct it by a reducing diet are usually unavailing because so many of these children prefer to eat normally rather than to lose weight. Insulin effectiveness is undoubtedly diminished if overnutrition is allowed to continue over long periods.

THE EFFECT OF THE HIGH CARBOHYDRATE DIET ON THE BLOOD SUGAR LEVEL

Although it is not invariably true, the blood sugar level is usually lower after the establishment of the high carbohydrate regimen than when a patient was receiving the low carbohydrate-high fat diet. This observation coincides with that of Rabinowitch.⁴ The diurnal variations of blood sugar are less extreme when patients are treated with the high carbohydrate-low fat regimen than when they are treated with other dietary regimens.

Insulin Reactions (Hypoglycemia)—These are less frequently observed in patients receiving the higher

TABLE 14—High Carbohydrate-Low Fat Diet in Case 9 (Sylvia L. S.)

so that in spite of continuous undernutrition a total loss of tolerance eventually takes place. In adults tolerance for food can be increased for much longer periods of time by treatment with undernutrition, but even in these cases a permanent increase is not obtainable. It must therefore be concluded that no permanent increase of food tolerance occurs as the result of undernutrition. Owing to the persistence with which a large group of clinicians still cling to the fallacious theory that undernutrition is a *sine qua non* of diabetic therapy (even after the discovery of insulin), treatment with high carbohydrate diets and insulin has been decried. As the result of my experience during the past ten years with diets high in carbohydrate and normal in calories, I have been convinced that this is the treatment of choice and

carbohydrate diets than when they receive the lower carbohydrate diets. It is my impression that these reactions are also less severe and less prolonged. Whether with low or with high carbohydrate diets, the best method of minimizing and in most instances of excluding insulin reactions is to require a division of the food into five or six feedings a day, particularly the carbohydrate content of the food.

Blood Cholesterol—As Rabinowitch⁴ has also demonstrated, one of the most striking features of the change from low to high carbohydrate diets has been the invariability with which a preexisting hypercholesterinemia can be reduced to normal blood cholesterol level. With various types of diet other than high carbohydrate, particularly when the fat of the diet con-

TABLE 15—High Carbohydrate-Low Fat Diet in Case 10 (William I.)

that the diabetic patient so treated enjoys better health with no observable detriment to the fundamental state of his diabetes.

Although an attempt was made to establish normal nutrition in all my insulin-treated cases of diabetes, I have also made an effort to avoid appreciable degrees of overnutrition. It has not always been easy to achieve this goal. The avoidance of overnutrition is desirable in all patients, and particularly in adults past middle age or in patients suffering from cardiovascular disease.

stitutes more than 50 per cent of the calories, there are a few patients who show a persistent hypercholesterinemia for many years. This occurs even in the absence of glycosuria, ketonuria and hyperglycemia. Its persistence is often striking even when the diet contains more grams of carbohydrate than fat. For example, patient 4 maintained a hypercholesterinemia for nearly two years. During the major portion of that time the average diet contained 130 Gm. of carbohydrate, 80 Gm. of protein and 90 Gm. of fat and in all other respects

his diabetes was under ideal control. Within six weeks after the diet was shifted to 250 Gm of carbohydrate, 80 Gm of protein and 80 Gm of fat the blood cholesterol fell to within normal limits and has remained at this level ever since. It will be observed that, although the ratio of total dextrose to fat in the first diet was 2 to 1, hypercholesterinemia continued until the ratio was changed to 3.8 to 1. I am able to cite fifteen other similar examples.

My experience leads me to the conclusion that there are no cases of persistent hypercholesterinemia which cannot be overcome by the administration of a high carbohydrate diet. The requisites for such diets, those which will overcome hypercholesterinemia, are as follows:

1 The number of grams of carbohydrate in such diets must bear the ratio of at least 3 and preferably 4 Gm to every 1 Gm of fat.

2 The diets must contain adequate calories for the maintenance of normal weight.

It has sometimes happened that after several years of treatment with these normal diets and the ratio of carbohydrate to fat as prescribed is 3 to 1 (or more), hypercholesterinemia has developed, but it has invariably been found that when this occurs the patients have either through carelessness been overeating in fat or undereating in carbohydrate. The same effect is, of course, obtained if patients ignore their urine tests over long periods of time so that glycosuria develops to such an extent that the available carbohydrate and its relation to the fat metabolized brings about a ratio of less than 3 Gm of carbohydrate to 1 Gm of fat in the total metabolic mixture.

Among the advantages of feeding high carbohydrate or normal diets as compared with lower or medium carbohydrate diets which have not so far been referred to are the following:

1 The majority of patients insist that they feel better.

2 Many of them remark that they possess so much more strength and physical endurance and they also feel that as far as their dietary habits are concerned they are like normal human beings.

3 They do not suffer from hunger and are therefore better patients as far as adherence to their dietary regimen is concerned.

SUMMARY AND CONCLUSION

1 Patients treated with high carbohydrate-low fat diets achieve greater effectiveness of insulin as judged by the ratio of units of insulin to grams of carbohydrate oxidized.

2 The administration of such diets overcomes hypercholesterinemia.

3 In the majority of instances, blood sugar levels are reduced after the administration of high carbohydrate diets.

4 Hyperinsulinism is less common and less severe.

5 Complicating conditions such as tuberculosis, gangrene and cardiovascular disease are less common when patients are being treated with the high carbohydrate diet (normal calories).⁶

6 After ten years of application of the high carbohydrate diet, the majority of patients show no loss of food tolerance or any other demonstrable retrogression of the diabetes.

INSULOGENIC STIMULATION OF SEXUAL DEVELOPMENT

GEORGE A WILLIAMS, MD

AND

ROBERT L WILLIAMS, BS

ATLANTA, GA

In spite of the exhaustive study of the pancreas and its hormones during recent years, data on the interrelationship of this organ with other endocrines are discouragingly conflicting. This is especially true with regard to the part played by the islands of Langerhans in the growth and development of the individual.

Bramwell¹ in 1904 and Moorhead² in 1920 described infantilism due to pancreatic insufficiency. It is highly probable, however, that their cases were due to general malnutrition and were not directly the result of malfunction of the pancreas.

Fig. 1.—Patient (at left) in a school group of the same age four months before insulin therapy.

Chabamer, Lebert and Lumiere³ conclude that insulin specifically stimulates growth processes and that accelerated development following its use is not dependent on improved general health. Lereboullet and Nobecourt³ do not share this view, however. Homans⁴ found that pancreatic pathologic changes in diabetes are limited to the beta cells of the islands and thought the alpha cells must have a special function. In American literature, Allen⁵ and others have suggested that the islands produce a trophic hormone, but most authors attribute results obtained from the use of insulin to improved nutrition, increased vitamin intake and other such factors. Frank and his co-workers⁶ in their

recent rather nihilistic summary of endocrine therapy in gynecology state that they are not convinced that insulin is of any value in that field.

Fleiderbaum⁷ has reported two cases of diabetes mellitus in which marked improvement in sexual development and function resulted from insulin therapy. Both patients were males, one an adolescent and the other an adult. He agrees with Allen that the islands produce a trophic hormone in addition to insulin and concludes that commercial insulin does not always con-

actively erectile, and the areolar glands were prominent. No tenderness or muscle resistance could be elicited in the abdomen, but the patient indicated that she had cramping pain in the midline low in the pelvis.

The abdominal pain ceased after a few days, but the breast fullness continued until September 14, when the abdominal pain recurred and the breast signs increased in intensity. At that time it was noted that the fat accumulation was assuming the adult feminine distribution in the pectoral, lower abdominal, perineal, gluteal and femoral regions (fig. 3). The facial appearance was that of an adolescent. There was a growth of fine hair over the forearms, in the axillae and on the mons pubis. The labia majora were fat and there was considerable vaginal secretion of the adult type. A satisfactory rectal examination was permitted and revealed the uterus low in the pelvis, normal in position and about the size to be expected in a girl of 11 or 12 years of age. No adnexal masses were detected.

It was presumed that the growth of secondary sexual characteristics and the apparent stimulation of the vaginal epithelium and uterus by estrogenic substance were due to insulogenic acceleration of anterior pituitary activity. The child being somewhat introspective, it was thought best to discontinue the use of insulin to spare her the possible ill effect of precocious menstruation on such an individual.

After withdrawal of the insulin there was no loss of fat, but the breast phenomenon promptly disappeared and the pelvic cramping did not recur. Steady gain in height and weight continued, but at a much slower rate. Ten months after insulin was omitted the functional breast tissue could not be dis-

Fig. 2—Influence of insulin on height, weight and secondary sexual characteristics.

tain both products of the gland. Fleiderbaum's cases are open to the usual criticism that improved body function, including growth and sex activity, are to be expected in diabetic patients properly treated with insulin. He suggests, however, that infantilism due to failure of the alpha cells without coexisting beta cell atrophy (diabetes) may occur.

The present case of insulogenic acceleration of development is reported because it occurred in a non-diabetic child as a result of the administration of insulin, and because the signs and symptoms of precocity promptly regressed when the use of insulin was discontinued.

REPORT OF CASE

A native white girl, aged 8½ years, had been markedly underweight and slightly underheight all her life (fig. 1). An only child, she was somewhat neurotic and had a poor appetite. Getting her to take sufficient nourishment had always been a problem to the mother. She had had the usual diseases of childhood without complications or sequelae and had experienced one severe attack of acute pyelitis.

Examination revealed a striking absence of subcutaneous fat and general underdevelopment for her age. Mentally, she was alert and active and was very successful in her school work. Blood count, blood Wassermann reaction, urinalyses, stool examination, Mantoux test and roentgen study of the chest were all essentially normal. Fasting blood sugar was found to be 95 mg. per hundred cubic centimeters.

No definite disease entity being discovered, administration of insulin, 5 units daily before breakfast, was begun July 10, 1933, to improve the appetite and increase the food intake. Little result was seen until the dosage of insulin was increased to 10 units daily before breakfast. The mother could not detect any appreciable improvement in appetite, but a remarkable increase in weight and height occurred (fig. 2). August 15 the patient complained of pain in both breasts and cramping pain in the lower part of the abdomen. Examination revealed that the mammary glands were enlarged and engorged. The parenchyma appeared as tense, flattened conical disks about 4.5 cm. in diameter and quite tender to palpation. The nipples were

Fig. 3—The patient eight weeks after institution of insulin therapy. Compare secondary sexual characteristics and facial appearance with figure 1.

tinguished from the mammary fat. The uterus was still low in the pelvis but had decreased one third in size. The adult type of vaginal secretion was not evident, and hair growth had regressed to its former stage.

Aug. 5, 1934, insulin was resumed in the former dosage. Within two weeks the patient had gained 2 pounds (0.9 Kg.) and the breast phenomena recurred. There was no cramping but she complained of a vaginal discharge which proved to be

typically adult in character. Increased hair growth on the pubis was noted. For the person before mentioned, insulin was discontinued, to be followed by an immediate disappearance of the breast and vaginal signs.

SUMMARY

Administration of insulin to a poorly developed non-diabetic girl $8\frac{1}{2}$ years of age resulted in striking acceleration of body growth and sexual development. This was manifested by increase in height and weight, stimulation of the mammary glands, ovaries and uterus, assumption of the adult type of fat distribution, and a growth of fine body hair. Discontinuance of insulin was followed by prompt regression of secondary sexual phenomena. Body growth continued, but at a less rapid rate. Resumption of insulin after a lapse of ten months resulted in prompt reappearance of the sexual phenomena, to regress as soon as insulin was again omitted.

384 Peachtree Street N. E.

THE CASE OF PATRICIA MAGUIRE

EUGENE F. TRAUT, MD

OAK PARK, ILL.

I am publishing the history of the case of Patricia Maguire because of the publicity attendant on it and because of the numerous inquiries concerning the patient. Its principal interest has been the prolonged period of somnolence.

Feb. 5, 1932, Patricia Maguire, a secretary and 26 years old, consulted me because of inability to stay awake. She had had a slight cold four days before. Her tonsils had been removed after several attacks of quinsy many years ago. She had had an uncomplicated, mild influenza in 1918. I had seen her and examined her completely at intervals since May 1930. In the course of these examinations her basal metabolic rate was determined to be normal, her sinuses were found clear by Dr. John Theobald. Urinalysis and blood counts had given normal results. On the last periodic examination, in November 1931, she presented normal conditions and had no complaints.

Her sleepiness, Feb. 5, 1932, consisted of inability to stay awake on elevated trains and drowsiness at work. She came to my office unaccompanied and was very alert. I was unable to detect any abnormalities in a complete examination. In particular there was no weakness of the extremities or the cranial nerves. Her temperature was 98 F and her pulse was 76. I referred her to an ophthalmologist who could detect no abnormalities.

The tendency to sleep increased. She complained of forgetfulness. She was brought to my office, February 15, with diplopia, left external strabismus and ptosis of both upper eyelids. Dr. Palmer Good reported slight contraction of the right visual field and normal vestibular responses. Her temperature, pulse and respiratory rate were normal.

She was sent to bed. Her spinal fluid was clear and under low pressure. It contained 870 cells, all lymphocytes. The Wassermann reaction was negative and the colloidal gold test 0000133320. The Ross-Jones test was faintly positive. The Kahn reaction was negative in the blood. Urinalysis showed no abnormalities. The hemoglobin was 76 per cent, the erythrocytes 4,500,000 and the leukocytes 11,000. February 17 her temperature was 99.4 F. She was irrational. The stupor increased so that she was unable to swallow. She

vomited occasionally, but the vomiting was not projectile. Nasal feeding was instituted on her third day in bed. Blood culture according to Clawson's method¹ yielded short diplococci after five days' incubation. On isolation, most of these were gram positive. Morphologically and culturally they resembled those described by Rosenow in the brains of encephalitis patients. Heavy intracerebral inoculations into rabbits caused stupor and flaccid paralysis of the hind legs after seventy-two hours in three of the five animals inoculated. The brains and cords of these animals showed minute punctate hemorrhages. During an observation of four months after intravenous injections of heavy suspensions of the blood organism, three rabbits showed no abnormalities. I later obtained similar organisms from the blood of two of three patients with acute encephalitis who had either been in St. Louis or had been in contact with St. Louis people at the time of the 1934 epidemic in that city. Cultures of the spinal fluid were grossly contaminated.

February 21 the rectal temperature had risen to 101 and the pulse was 92. February 25 the temperature was 101.6 rectally and the pulse was 100. She had involuntary urinations and defecations. The temperature continued to rise to 104 rectally and the pulse to 120. Vomiting became projectile. The optic disks swelled slightly.

February 27, Dr. Peter Bassoe found the following conditions. The patient was in a deep stupor but responded a little to supra-orbital pressure by drawing the arms and legs up. There was no neck stiffness, and Kernig's sign was negative. The pupils were small and reacted normally. The eye grounds were normal. The wrist, elbow and knee reflexes were normal. There was a slight ankle clonus on both sides. A Babinski sign was present on the right side. The abdominal reflexes were present but weak. Lumbar puncture yielded a clear fluid under definitely increased pressure. He confirmed my diagnosis of acute epidemic encephalitis.

She developed generalized rigidity of the "extrapyramidal" type. Projectile vomiting continued with the fever. This febrile state lasted from Feb. 17 to March 8, 1932. The fever had a gradual rise to 103, where it remained for three weeks and then gradually descended to normal. There were elevations of fever 1 or 2 degrees occasionally for three weeks following the continued fever. As the fever disappeared, the rigidity relaxed. She twitched and jerked at intervals. Any of her extremities would have a short, generalized clonic spasm. These convulsive movements were often marked enough to throw her out of bed. She yawned a great deal and grimaced, holding her mouth pulled up at either side. She would not answer but would draw away from painful stimuli. Convulsive movements of the jaws required the insertion of a gag to protect her tongue and cheeks. She lay for hours with the neck, arms and legs acutely and rigidly flexed. During this time (in the first part of March 1932) the deep reflexes were brisk. The abdominal reflexes were absent. Babinski's sign was positive bilaterally. The eyes remained immobile to light. The swelling of the optic disks receded. During the acutely febrile part of her illness treatment consisted of nursing care, repeated spinal drainages, intravenous injections of 50 per cent dextrose in amounts varying from 50 to 100 cc. and sodium cacodylate intravenously.

¹ Traut, E. F. Blood Cultures in Chronic Arthritis. *J. Infect. Dis.* 52: 230-235 (March-April) 1933.

In April 1932 her eyes would follow a light. She swallowed fluids poured into her mouth through the catheter. She did not respond to sound but would be roused to restless movement by noise and would squirm about and groan. A culture of the blood yielded no growth.

A liquid diet affording 2,500 calories and 3,000 cc of fluid was administered through a nasal catheter for two months. It consisted of four codded eggs, 1 pint of milk, one pint of cream, the juice of six oranges, cooked cereal thin custard, vegetable soup and brewers' yeast. After the fever subsided one-half ounce (15 cc) of cod liver oil was added. She gained weight so rapidly that the caloric value had to be reduced.

When swallowing returned the catheter was placed in her mouth. She still drinks in this manner, lying on her back with her head turned to the side.

She had slight elevation of the temperature and pulse for months after the acute febrile period had passed. From July 9 to Sept 7, 1932 she was given subcutaneous injections of a whole killed bacterial suspension made from the organisms found in her blood. The first injection was 10 million organisms and the final dose was one billion. The vaccine was given twice weekly. Neither local nor general effects were noted.

The vomiting relieved by alkalis and milk was often preceded by movements suggesting epigastric pain. The vomiting would be followed by relaxation and rest. Particularly when, Sept 7, 1932, blood was vomited, it was felt that the patient was suffering from peptic ulcer due to brain injury.² The vomiting stopped promptly on institution of a modified Sippy ulcer management. The vomiting recurred on discontinuance of the alkalis and milk and again was controlled by ulcer management.

In January 1933 she would protrude her tongue when requested. This was the first definite sign of hearing or understanding. In February 1933 she had a chill and a fever of 105 with pneumonia involving the whole lower lobe of the right lung. She became very cyanotic. She was placed in an oxygen tent and given Felton's antipneumococcus serum types I and II intravenously. She received 40,000 units within twelve hours of the initial chill. Her pulse and respiration stopped while the serum was being given. Epinephrine hypodermically resuscitated her. In the following twelve hours she received 40,000 units. Within seventy-two hours of the onset of pneumonia she had a normal temperature, normal pulse and normal respiratory rate. Auscultation showed resolution. Her convalescence from the pneumonia was uneventful. Anterior Pituitary Liquid (Armour) was given hypodermically on alternate days with a daily oral dose of 2 grains (0.13 Gm) of whole thyroid. Two weeks of this regimen produced no change in the patient.

Blood was drawn from the patient's arm and given intramuscularly in her buttock in doses increasing from 5 cc to 20 cc without altering her condition.

Dr W J Potts transfused 500 cc of blood directly from her healthy stepfather into the patient without effect. The patient was given intravenous and intraspinal injections of serum from two individuals who had had encephalitis eight and ten years ago. The serums were not pooled. In all, 250 cc of these serums was given intraspinally in sixteen injections and 1,050 cc was given intravenously in the same number of injections. An intravenous and an intraspinal injection

was given twice weekly. An amount of spinal fluid was always removed slightly exceeding the amount of serum injected. Such injections were regularly followed by a chill and fever of 102. At the termination of the serum therapy she was more alert and would resist and pull away from painful stimuli.

Ten cc of Pregl's solution of iodine was injected intravenously twice weekly for three weeks without any change in the patient's condition.

Fifteen chills at semiweekly and weekly intervals were induced by intravenous typhoid vaccine. She seemed unchanged after these injections.

Colloidal sulphur (Diasporal) was injected intramuscularly twice weekly for five weeks, 0.15 Gm and 0.3 Gm of neoarsphenamine were given intravenously without apparent effect.

As measured by her ability to utilize 100 Gm of dextrose by mouth, her sugar tolerance was moderately decreased. There was no glycosuria. The figures were 108 mg of dextrose taken starving, 154 mg one-half hour after the dextrose, 192 mg one and one-half hours after the oral sugar, and 150 mg two and one-half hours after the dextrose. Such a disturbance in the carbohydrate metabolism is common to many chronic infections.

She was given fever in a cabinet heated with a large infra-red unit. The fever varied from 101 to 104 F rectally for 136 hours between September 1933 and March 1934. Each treatment lasted four hours. She had three attacks of heat shock while taking the fever treatments. Because of these and because no immediately favorable response to the fever was noted, the hyperpyrexia was discontinued.

Scopolamine, $\frac{1}{100}$ grain (0.00065 Gm), was given four times daily with improvement in the drooling. It is occasionally given at night for restlessness.

During the last seventeen months there have been signs of returning intelligence. For over a year she has grunted and rolled about when she desires to void. She has been in stupor about 80 per cent of the time from 5 a m to 8 p m. During the night she is apparently in a deep natural sleep. During the day she lies for the most of the time with tensely flexed arms and closed eyes, with her head turned to the side. She drools. If aroused by the entrance of some one she may look at the person and then more firmly flex her arms, make athetoid movements with the thumbs and fingers, hyperextend the left great toe and grimace. The grimace consists of pulling the right corner of her mouth up and pulling the left corner down. Meanwhile she focuses the right eye. The left eye is everted. She rolls about, groaning. The pupils are equal, regular, moderately contracted and respond in accommodation. They do not respond to light. The wrists are flexed and the fingers clench the flexed thumbs. She has recently been awake for eight or ten hours of the day with the eyes open and an alert expression. Excepting for the failure of the pupils to react to light and the ability to move the right eye past the midline to the left, there is no cranial nerve involvement. All the deep reflexes are present and of normal amplitude. The abdominal reflexes are absent. The right plantar response is a normal flexion. The left plantar reflex consists in further extension of the already extended left great toe. The bowels are emptied by a daily enema. She will protrude her tongue and follow a finger with her eyes. She will blink her eyes if a finger is thrust at them. If her arm or leg is rotated and she is directed to hold the extremity still

2. Cushing, Harvey. Peptic Ulcers and the Interbrain. Surg. Gynec. & Obst. 55: 1 (July) 1932.

after twenty rotations, she will stiffen the arm or leg at the proper time without being informed of the number of rotations made. She will grasp a finger or, at times, raise her hand or smile on demand. She will read and follow these commands if written on a slate. When asked how many children various families had when she became ill, she designates the correct number by raised fingers. When told of additions to these families within the last three years she will give the correct new number if asked several days following the time she was informed. She also signaled that her uncle had died two years ago. She has recently held her head up while sitting. She watches people working in her room. She will stop eating to investigate the actions of another person in the room. She nods the head to answer a question in the affirmative. When asked how many of five apples remained after selling two, she raises three fingers. She responds best to her mother's request. She apparently distinguishes her mother from others.

She has a normal appearance and proportions when relaxed. The rectal temperature varies from 98 to 99.6. The pulse is 80 and regular. There has been a gradually developing asymmetry of the legs. The right leg is one-half inch shorter and the right thigh is one inch less in circumference than the left. The patient moves the right leg more than the left. Massage and passive motion have failed to remove this asymmetry. Her hair distribution has not altered. Her state of nutrition can be altered at will by her food intake. Menstruation ceased at the onset of the illness. It returned and has been normal for six months.

DIFFERENTIAL DIAGNOSIS

The patient never had neck rigidity or Kernig's sign. The stormy febrile onset, lack of focal symptoms or signs with minimal and quickly disappearing edema of the optic disks have been points against the presumption of cerebral tumor. Her continued improvement is more significant evidence against cerebral neoplasm. Her grimaces and lack of speech suggesting catatonia are accompanied by a pupil practically immobile, right rectus palsy and positive Babinski signs ruling out catatonia, hysteria and malingering. The mode of onset and the nature and grouping of symptoms are of the kind common in epidemic encephalitis. The unusual feature is the long duration of the somnolent stage.

SUMMARY

Within a period of three weeks a young, previously healthy woman developed stupor accompanied by fever, leukocytosis and bacteremia. The spinal fluid was clear but showed pleocytosis, increased globulin and an abnormal colloidal gold curve. The febrile stage and the deep stupor lasted three weeks. Various chemicals, vaccines, serums and hyperpyrexia were used. They are not known to have altered the course of the illness. Excepting occasionally scopolamine for sleep, she has had no medication since Feb. 28, 1934. She was given more than 1,000 feedings by nasal catheter without developing aspiration complications.

The patient is very well nourished and has good color. Her muscles are large and strong. She has not spoken or made any purposeful movements except those of defense. She lies inattentive with shut eyes most of the time. The pupils do not react to light or in accommodation. The left great toe is constantly and rigidly hyperextended. She is fed by spoon or a catheter in the mouth.

CORONARY ARTERY THROMBOSIS WITH PERICARDIAL EFFUSION

A. M. MASTER, M.D.

AND

HARRY L. JAFFE, M.D.

NEW YORK

Within a short period of six months two cases of pericardial effusion following coronary artery occlusion have been observed. It is thought that this condition may be diagnosed clinically and that it is one which will be found more frequently.

The reported incidence is indeed small. In a review of the etiology of 360 cases of pericarditis, Gerke¹ did not mention coronary artery occlusion. In Levine's monograph² on coronary thrombosis a pericardial effusion was encountered in only one patient in a series of 145. This effusion was not suspected during life, but 1,000 cc of pericardial fluid was found at postmortem examination. White³ in his book on heart disease did not cite coronary artery thrombosis as a cause of pericarditis with effusion. However, in 1932 Camp and White⁴ reported their observations in 126 cases of pericardial effusion, and in two cases in which death occurred with evidence of chronic passive congestion, an associated coronary occlusion was found. In the same year Smith and Willius,⁵ in the postmortem examinations of sixty individuals who had pericarditis with effusion remarked that in two cases there was acute cardiac infarction the result of coronary thrombosis. It will be seen that, although the literature on the subject is small there is evidence that coronary artery thrombosis with pericardial effusion may be found at postmortem but missed during life. The following two patients survived and it is thought that more such cases will be observed if the foregoing facts are kept in mind.

CASE 1—An obese, well preserved brewer aged 60, admitted Sept. 21, 1933 and discharged Nov. 19, 1933, had acquired syphilis at the age of 23 years, but after treatment the Wassermann reaction had become negative. Eight years before admission to the hospital he had experienced precordial oppression and dyspnea constantly for several months, since then these complaints had been occasioned by exertion. He was found to have arterial hypertension. Three weeks prior to admission he was suddenly seized with sharp precordial pain radiating to the shoulder associated with extreme dyspnea and sweating. After several days he was again comfortable. However, the symptoms recurred one week before admission with such intensity as to force the patient to bed. He entered the hospital in extreme dyspnea and orthopnea, with cyanotic ashen facies and marmorated skin. The cervical veins were dilated. Fine rales were heard at both bases. The left border of the heart was almost at the anterior axillary line, the right border 2 cm. beyond the sternum. The cardiac rhythm was entirely irregular the rate 140 beats per minute. There were a rough systolic-diastolic murmur and thrill at the aortic area, which became faint at the apex. The liver percussed 2 cm. below the costal margin there was no edema of the feet. The blood pressure was 175 systolic, 65 diastolic. The blood contained 20,000 white blood cells per cubic millimeter of which 84 per cent were polymorphonuclears. The Wassermann reaction was negative.

From the Cardiovascular Service and the Medical Services of Dr. George Baehr and Dr. B. S. Oppenheimer, Mount Sinai Hospital.

⁵ Smith, H. L. and Willius, F. A. Pericarditis. III. Pericarditis with Effusion. Arch. Int. Med. 60:192 (Aug.) 1932.

During the next week the condition of the patient continued to be critical. The cardiac rhythm was rapid with frequent periods of auricular fibrillation despite intensive digitalis administration. The blood pressure gradually fell to 118 systolic, 26 diastolic. An x-ray film of the chest (fig. 1A) showed massive enlargement of the heart shadow, the left border extended to the chest wall the right beyond the midclavicular line. Rapid improvement followed. A week later a loud pericardial rub was present over the entire precordium and this slowly disappeared during the next month. The size of the heart gradually diminished (fig. 1B) and the patient went on to complete recovery. The cardiac rhythm became regular but the systolic diastolic murmur remained.

The electrocardiogram taken on the first day and for some time thereafter revealed auricular fibrillation, left ventricular preponderance, slurring, and low voltage of the QRS group, with occasional ventricular premature beats (extrasystoles). The T waves were inverted in leads I and II. A record about ten days later revealed restoration of regular sinus rhythm.

CASE 2—An obese American woman aged 57 whose past history was not remarkable admitted March 8, 1934, and discharged April 3, 1934, was seized with sharp pain over the left chest anteriorly while hurrying up a flight of stairs. She was forced to rest because her chest seemed to be tied in a knot. After several minutes the pain was replaced by soreness except when she bent forward at which time she experienced pain over the precordium radiating upward to the neck. Two days later she became irascible and vomited; she felt weak and chilly. During the next few days the substernal pain persisted. In addition there was pain in the left axilla and about the scapula especially on breathing. On admission the patient was acutely ill and moderately dyspneic. The temperature was 102 F, the pulse 120 beats per minute, the blood pressure 128 systolic, 72 diastolic. Over the left lower lobe were dullness, distant bronchial breathing and voice and moist rales. There was a gallop rhythm at the cardiac apex. The white blood count was 8900 with polymorphonuclears 76 per cent. The basal metabolism was normal. The admission diagnosis was pneumonia possibly associated with acute coronary occlusion. However, an x-ray film of the chest (fig. 2A) showed distinct enlargement of the heart shadow to the left which raised the suspicion of pericarditis with effusion. This was confirmed by the appearance of a friction rub to the left of the sternum on the second day after admission. After two days this could no longer be heard and a week later the chest film (fig. 2B)

Fig. 1 (case 1)—A, pericardial effusion following coronary thrombosis, Sep. 27, 1933; B, disappearance of pericardial effusion, Nov. 3, 1933.

revealed the heart to be of normal size. During this time the temperature had fallen rapidly and the general condition of the patient had improved. The blood pressure had fallen to 98 systolic, 64 diastolic. At no time was digitalis administered. Except for occasional pain in the chest the patient convalesced uneventfully. The cardiac sounds assumed a good quality. At fluoroscopy before discharge no abnormality was observed in the heart or lungs.

The patient was seen again three and a half months later. She complained of precordial pressure following effort and shortness of breath on slight exertion. She was unable to climb stairs at all. Clinically and roentgenographically there was no evidence of cardiac or pulmonary disease. The blood pressure was 128 systolic, 80 diastolic.

An electrocardiogram taken the day following admission showed normal sinus rhythm, with a rate about 105 per minute. Left ventricular preponderance was present. The voltage of the QRS waves was low. The record on March 25, 1934, disclosed inverted T waves in leads II and III. In a few days the T waves had practically become upright.

COMMENT

The evidence in both cases appears fairly conclusive that the pericardial effusion was due to an acute coronary artery occlusion. In the first case an acute illness was present in a man of 60, with a previous history of

Fig. 2 (case 2)—A, pericardial effusion following coronary thrombosis, March 9, 1934; B, disappearance of pericardial effusion, March 15, 1934.

syphilis but no story or evidence of rheumatic fever or rheumatic heart disease. There was also no reason to consider the diagnosis of tuberculosis. On the other hand, the history was typical of coronary artery thrombosis in a patient with arterial hypertension. The x-ray film and pericardial rub were proof of a pericarditis with effusion.

In the second case, the woman aged 57, the question arose during her hospital stay whether or not the lung signs were those of pneumonia and hence whether the pericarditis with effusion was a complication of the pneumonia. Pain over the chest, even in the precordial region, may be present in a patient suffering from pneumonia. Clinically, however, the patient's course was not that of pneumonia. In fact, a pericardial effusion in a pneumonia⁶ patient is commonly associated with an empyema, the patient's condition is grave and the outcome is usually fatal. Our patient never presented such a picture. Further proof that coronary artery disease was the basis of her trouble was observed June 21, 1934, when she returned to the hospital for reexamination. She complained of precordial pressure following the slightest physical exertion. The electrocardiogram corroborated the diagnosis, for it still showed evidence of myocardial damage.

It may be thought that instead of a pericardial effusion a hemopericardium⁷ occurred in our cases. This is hard to disprove completely, as the patients survived and paracentesis was not performed during life. However, the course in hemopericardium is usually rapid and fatal.

SUMMARY

Pericardial effusion may follow an acute coronary artery occlusion. In two cases reported, both patients recovered.

6. Stone, W. J. Pericarditis as a Complication in Pneumonia. Based on Three Hundred Necropsies. *J. A. M. A.* 73:254 (July 26) 1919.
7. Olcott, C. T. Rupture of a Coronary Artery. Hemopericardium. *New England J. Med.* 204:760 (April 9) 1931.

In a patient suffering from an acute coronary thrombosis a large area of cardiac dullness should arouse the suspicion of a pericardial effusion, particularly when a pericardial friction rub accompanies this enlarged heart.

The diagnosis of coronary thrombosis with pericardial effusion will be made more frequently if roentgenograms are taken.

REPAIR OF BLADDER FISTULAS

CLOSURE IN SEVENTEEN CONSECUTIVE CASES

EDGAR I. SCHMITZ, M.D.

ST. LOUIS

This paper contains a report of seventeen consecutive cases of bladder fistula successfully closed together with a discussion of their causative factors, types of injuries sustained and the principles of operative procedure employed.

The following cases were encountered:

- (One vesico uterine (fundus))
- Two vesicocervical
- (One vesico urethrovaginal)
- Three large vesicovaginal, the opening being larger than a half dollar (30 mm.)
- Nine small vesicovaginal (quill to finger size)
- One anterior vesical injury (fistula under the symphysis pubis)

Grouping them according to causative factors discloses the disturbing fact that practically all these injuries were sustained by direct trauma, of a more or less preventable character. They may be classified as follows:

- Eight fistulas following hysterectomies
- One following criminal abortion
- One after a cervical amputation
- One following cystocele repair
- Five due to obstetric manipulation
- One following radium for carcinoma of the cervix

These various injuries merit discussion, for after critical examination only two cases can be unequivocally classed as excusable because of the nature of the trauma sustained. One of these involved the delivery of a double monster, in which a cervical injury resulted, the other was a slough following the application of radium to a large cancer. This leaves a residuum of fifteen holes in the bladder that should have been prevented by proper surgical technic. Grouping these fifteen cases reveals that, of the eight fistulas following hysterectomies, four were predicated on a mistaken diagnosis, the uterus having been removed for cancer where no malignant process was found. All eight sustained direct violence to the bladder wall, as urine appeared in the vagina within twenty-four hours following the operation. The criminal abortion fistula was produced by scraping away a portion of the anterior uterine wall with a sharp curet and piercing the bladder with the same instrument. In the cervical amputation and cystocele repair cases the injury was obviously sustained while an attempt was being made to free the bladder from the cervix.

The four remaining obstetric cases included gross negligence by a midwife who deserted a case of breech presentation when she could not deliver the aftercoming

head, and lack of judgment on the part of the physician, who some hours later extracted the dead baby too forcibly for the already badly damaged tissue. The resulting injury left a defect at the base of the bladder through which four fingers could be easily passed. The second obstetric injury was sustained by attempting to pierce the head of a hydrocephalic infant and pushing the scissors through into the bladder cavity. A third childbirth injury was the faulty application of forceps to the head of an unusually large baby and the use of the pubic bones as a fulcrum for a prying extraction. The result was a dead child, separation of the symphysis pubis, a tear into the bladder under the symphysis, and a third degree laceration. The fourth obstetric case again involved the faulty use of forceps, this time tearing out the base of the bladder at the site of the sphincter muscle and stripping away the upper third of the urethra.

While the obstetric cases are no doubt more dramatic in their recital, they comprise the smaller number of fistulas produced and give no more terrifying symptoms to the patient than the prosaically chronicled injuries sustained at operation. Such a recital of facts (fifteen of seventeen cases could be classed as preventable injuries) is not a pleasant task. Admitting that in every operative field accidents will occasionally happen, still the number of failures in this series seems unduly large. Yet these failures form the basis of my paper, for without the trauma there would be no fistula.

Viewing the cases from the standpoint of operative difficulties encountered, I found that the eight fistulas following hysterectomy were all small openings, as might have been expected. These fistulas were complicated mainly by two factors: the nearness of the hole to the ureters, or the inaccessibility of the traumatized area owing to its being pulled high into the vaginal vault by the scar of the fixation. The three large fistulas, regardless of cause, were all low in the bladder, showed marked tendency to incrustation and retraction, and were difficult to close mainly from the standpoint of freeing enough tissue to bring about free mobilization of the structures to be sutured.

The remaining six cases, each in its own peculiar way, brought about problems of closure that cannot be fitted into any one descriptive picture. The general principles of repair about to be mentioned, however, apply in this group as well as the others. In dealing with the entire fistula problem it must be remembered that each operator must bring to his case some modicum of ingenuity and dexterity in the matter of technic, for on these factors the successful outcome in special cases largely depends.

The prevention of fistulas is perhaps not strictly a part of a paper of this character, but in view of the fact that all these cases are traumatic in origin it might not be amiss to suggest that a disposition to proceed with care when the field of operation is not clearly defined will obviate practically all these unfortunate accidents. Should a hole inadvertently be made in the vesical wall, an immediate painstaking repair will almost certainly close the defect.

METHOD OF CLOSURE

Turning now to the problem of closure, certain basic facts must be established and certain procedures carried out before any operation can be undertaken. First and foremost in this matter is the qualification of the surgeon to carry to his case the necessary patience and

training so obviously needed in this type of work. One of the greatest causes of failure in fistula operations must be attributed to a lack of understanding of the problems involved by the person who first attempts to close the opening. The percentage of bad results mounts rapidly after each attempted closure. Undue haste in operating and a lack of willingness to work out slowly and painstakingly each bit of tissue needed contribute to failure.

The time to close a fistula is at the first sitting, and all vanity and professional squirmishness should be set aside to the end that a case of this kind may get into proper hands from the very beginning and not after an unsuccessful attempt to close has seriously jeopardized the patient's chances for a prompt and complete recovery. A few figures from my series will illustrate this point. Thirteen of seventeen fistulas were closed by one operation. Of these thirteen cases, no previous attempts at closure had been made in ten. Two patients had been unsuccessfully operated on once before and one patient twice. Thus by far the largest number of fistulas closed at one sitting had not previously been subjected to harmful tissue trauma.

Of the four remaining cases, it took two operations to close the fistula in two, although no procedure had antedated my attempted and then final closure, and two patients had more than one operation before coming under my care and each took two sittings before closure was accomplished. To recapitulate, thirteen cases in my hands were primary closures and two operations each were needed in four to seal the opening. The inference is then clear that the surgeon who has the opportunity to officiate at the first repair operation is in the most strategic position to close the defect.

Certain points in the preparation of any case of vesical fistula are so axiomatic that they need not be elaborated on here. Suffice it to say that all ulcerated areas in the genital canal must of necessity be healed before any operative procedure is resorted to, that calcareous deposits should be removed as nearly as possible and that bladder infection should be reduced to a minimum.

The services of a competent urologist are indispensable in the type of work under discussion, for not only must the location of the opening in the bladder be accurately located by cystoscopic examination but its relation to the ureters and the patency of these structures should be ascertained. It is all important to know as much or more of what the intravesical picture shows as it is to locate the external opening properly. No blind operation should ever be attempted.

Having located the opening externally and internally and having carefully planned the procedure, one is now in a position to operate. Again I stress the factor of time. If one must hurry, one should not start. Haste causes failure. In all of my cases with one exception, closure was done from below. The vaginal route for those accustomed to gynecologic procedure is the safest mode of approach, for it not only enables one to free the vaginal scar completely but also permits of wide dissection, which in the end secures a firmer closure and restores the supporting structures to approximately their normal relations. In only one case was it necessary to resort to a paravaginal or so-called Schuchhardt incision. With proper retractors, even high fistulas can usually be satisfactorily reached without creating an additional wound in the pelvic floor.

The secret of success in the closure of vesical fistulas is undoubtedly dependent on many factors, but one or two points have shown themselves to be very much worth while if any uniformly satisfactory results are to be obtained. The first of these is not to freshen the edges of the defect. In most textbooks dealing with fistulas the suggestion is made that after the tract is freed the hard, firm edges of the opening should be carefully cut away. If I were to put only one don't in this paper I should apply it here. Don't cut anything away. Don't sacrifice the least bit of bladder wall. All the tissue is needed that one can get. Free the edges and turn them in, bring the raw surfaces together as near the free margin as possible, but don't cut any portion of the bladder away. By saving all tissue, if a failure should result, the opening will not be any bigger than the original defect and the patient will be no worse off in that respect than before operation. If one freshens the edges, the hole is made larger, and should there be failure to close, any operative procedure that follows will be made just that much harder if not impossible. I fear that many failures can be chalked down to this error of technic, for as operation follows operation in bad cases the opening continues to enlarge, which surely is the worst possible outcome for the patient.

My second point is a plea for free and wide dissection of all possible surrounding tissue. If one wishes to succeed in closures, suturing must be made not only possible but practical. No suture will hold in soft tissue under tension, and the only way to avoid tension is to mobilize structures. To attempt a closure of a fistulous tract with the slightest tension on the suture line because of inadequate preliminary dissection is to court disaster from the start. There must be sufficient bladder wall available not only to allow a closure of the opening but also to permit the placing of one or two rows of supporting sutures. To accomplish this necessitates a thorough understanding of the problem in hand and a willingness to free tissue in all directions. Only by carrying out a well planned and systematic dissection can one mobilize sufficient vesical wall to close the larger or more inaccessible bladder fistulas.

The manner of placing sutures is important in two ways. A pucker should never be caused. If tissue buckles, surface adaptation is interfered with and the results are jeopardized. If working near the ureters, one should place the suture so that it follows the long axis of the tube and does not cross it. In this way if one should get too close to the lumen not as much harm will result. A nonabsorbable suture should never be used in the bladder. If the catgut does not hold, it is almost surely a fault in the operative technic and not the suture material that should carry the blame. In my work I prefer an extra hard fine gut, such as is used for intestinal suturing, and find it very satisfactory. Another important point in the suturing of these wounds is the obliteration of all dead spaces. One must suture the deeper to the more superficial structures or pockets will develop, which may undo the best operative procedure.

AFTER-TREATMENT

After the incision has been closed in a satisfactory manner, several additional points in technic are necessary before everything has been done for the patient that makes for success and minimizes failure. An iodoform pack is placed in the vagina along the suture line. This to a degree prevents oozing and aids in holding

the raw surfaces to one another. It has the additional advantage of reducing the bacterial flora to a minimum during the early postoperative period. It should, however, be removed at the end of twenty-four hours, as it may otherwise cause irritation. A catheter is always introduced into the bladder at the end of the operation and fixed there. In all my cases I have sewed this catheter into position by means of a bit of silkworm gut passed through the small labia near the urethra. This serves a double purpose. It not only fixes the catheter but keeps the patient quiet and thus the catheter from moving. If the body is moved it causes pain, so that these patients remain relatively quiet in one position for several days, which accomplishes much. I never use a so-called mushroom catheter but always a straight one, as it can be removed more easily and works just as well. The catheter is allowed to remain in the bladder for at least a week, preferably ten days, although it may be necessary to clip the stitches that hold it fast before this time and substitute taping.

Posture is so important a part of the after-treatment in these cases that a word about it should be said here. One must try to drain away as much urine from the suture line as possible, not as was formerly suggested to keep the bladder incision dry but to prevent even the very slightest pressure on the repaired area. If there is only a tiny bit of constant fluid pressure, seepage may occur. To obviate this one should make the most dependent portion of the bladder that area farthest away from the suture line. In other words, in all posterior fistulas and this means practically all of them the patient should be placed flat on the abdomen, with the head of the bed slightly elevated. This position must be maintained for at least five days, no matter how uncomfortable the patient may be. After this a little lying on the side and gradual turning to the back is allowed, but a minimum of five days of abdominal position is in my opinion essential in all posterior fistulas.

NURSING CARE

Lastly, the nursing care of these patients must be not only good but perfect. The drip of the catheter must be under constant observation so that no possible backing up of urine can occur as the result of blockage. Back pressure is fatal to the result. The catheter itself is run down between the patient's legs and out at the foot end of the bed, never over the side. I do this because I want the urine to fall gradually by gravity to the bottle and not by any chance be forced to flow over even a slight elevation. The tube is protected by sand bags, so that the lower limbs have no chance to compress the lumen. It is irrigated once or twice daily with boric acid solution, which serves the double purpose of keeping the catheter clean and allaying vesical irritation.

CONCLUSION

The technic I have outlined has given me good results and I trust may prove useful to others. From what has been said it will be seen that success in the closure of bladder fistulas is dependent on a multiplicity of detail, every step of which must be painstakingly carried out. Even with the best technic a certain number of failures will no doubt be recorded, but it should be the aim of the operator to plan an approach to this problem in such a way that the tragedy of persistent failure will be rare indeed.

OTOSCLEROSIS IN IDENTICAL TWINS

GEORGE E. SHAMBAUGH, JR., M.D.
CHICAGO

Otosclerosis is the most important cause for severe deafness coming on in early or middle adult life. The pathology, the clinical picture, the diagnosis and the prognosis of the disease and its relative frequency were accurately described by Bezold, who in 1885 was the first to show that the characteristic clinical picture is due to bony ankylosis of the stapes. The acceptance of these facts however, particularly concerning the frequency of otosclerosis, has been slow, especially in this country where histologic examination of temporal bones was until recently limited to a very few investigators. Seeing is believing, and, as the microscopic study of temporal bones is being carried out more extensively and in more places, the accuracy of the observations of Bezold, Siebenmann and others that otosclerosis is a very common disease is beginning to be appreciated.

Knowledge of the etiology of this very important cause for progressive deafness has advanced but little since Bezold's time. The strong hereditary tendency has from the first suggested that the foci of spongification in the bony capsule of the labyrinth are the result of an inherited change and this view has been enhanced by the recent finding of a characteristic focus of otosclerosis before birth. That the occurrence of otosclerosis invariably follows mendelian laws has not been satisfactorily established, but the hereditary tendency is so striking that one may be justified in assuming that the hereditary factor is necessary for the development of otosclerosis.

The question at once arises: May there not be other extrinsic factors within our control which favor and accelerate the development of this inherited lesion? Pregnancy is just such a factor which in a certain proportion of women with otosclerosis acts apparently as an activator or accelerator of the lesion. That there may be other external factors is suggested by the fact that the progress of deafness in a given case of otosclerosis is not even and regular but is marked by periods of activity when the hearing decreases comparatively rapidly and periods of quiescence when the hearing may remain practically stationary for years. The discovery of these factors is extremely important but extremely difficult, owing to the essential slowness of the development of the process in which many years may elapse between beginning and complete ankylosis of the stapes. Search for possible endocrine imbalance, disturbances in mineral metabolism or dietary deficiency has thus far been negative. Histologic study, while confirming the view that otosclerotic foci have periods of activity and periods of quiescence, has failed to give a clue to the factors causing these periods of activity.

As I¹ pointed out in 1933, otosclerosis occurring in identical twins affords a unique opportunity to study this disease. The hereditary factor in each of a pair of identical twins is exactly equal, so that if otosclerosis develops unequally or develops in one and fails to develop in the other there presumably is some extrinsic or nonhereditary factor responsible for this difference, and by carefully examining the histories of each twin one may be able to uncover the extrinsic

¹ Shambaugh, G. E., Jr. Progressive Deafness in Identical Twins. Arch. Otol. 17: 179 (Feb.) 1933.

etiologic factor present in the one and absent in the other. On the other hand, if otosclerosis always develops simultaneously and runs an identical course in identical twins irrespective of differences in their environment, general health and illnesses, then it must be concluded that heredity is the sole etiologic factor in the development and progress of a case of otosclerosis.

The first report of otosclerosis in identical twins appeared in 1932 in the German literature.² The case report was briefly as follows: Two brothers, identical twins, aged 39 years, had experienced very different upbringings. One went abroad as a merchant in his early youth, the other studied and settled down in a small town in middle Germany as a dentist. At the age of 36 both became aware of increasing deafness and tinnitus. The difficulty in hearing increased gradually and symmetrically in both ears. At the time of examination three years later both suffered from a severe deafness. This was found to be due to otosclerosis with primary stapes fixation. The hearing curves of both brothers corresponded almost exactly. In this instance, although the living conditions, climatic influences, environment and occupations were basically different, the development of otosclerosis ran an identical course in the two. The author concludes on the basis of this one observation that the hereditary anlage is the essential and controlling influence in the development of otosclerosis compared to which the outside influences are of subordinate significance.

The second case of otosclerosis in identical twins was reported by Frank H. Rodin³ in 1933. The history was as follows: Two identical twin sisters, aged 15 years, had grown up together and had had the same illnesses at the same time (scarlet fever and whooping cough). At the age of 6 the hearing of both began to decrease gradually until about three years before the examination, when it had become stationary and had not changed since then. Examination revealed essentially normal drum membranes with the tuning fork reactions of conduction deafness and a practically identical hearing defect in the two twins. In this set of identical twins the defect also ran an identical course but, unlike the first set, here the environment, illnesses and general health were also identical, so one cannot conclude that different outside factors might not have altered the course of the disease.

To these two instances of otosclerosis in identical twins I can now add three more, which I have had the opportunity of examining the past year.

1. The first set of identical twins I encountered in an examination of the members of the Washington, D. C., League for the Hard of Hearing carried out in May 1933. Nora and Elizabeth, aged 41, were so much alike in every respect as children that their friends, their teachers and even their father had great difficulty in telling them apart (fig 1). They were the eldest of five children, all daughters. They gave a very unusual family history of deafness in that both parents, all five daughters, and a maternal aunt suffered from progressive deafness. Fortunately I was able to examine the one living parent and two of the daughters in addition to the twins. The results of these examinations were briefly as follows:

The mother of the twins began to notice gradual loss of hearing soon after the age of 8 and this had been progressive, especially the last twenty years. She was profoundly deaf at 68, at the time of examination with a negative Rinne test in both ears and prolonged bone conduction. Both drum membranes were entirely normal except for a slight loss of luster

on one side. The diagnosis was otosclerosis with primary stapes fixation.

The youngest daughter began to notice very gradual loss of hearing at the age of 17, and this has progressed especially the past four years so that at the age of 29 at my examination, there was a moderate defect in hearing with more impairment of the low tones than of the high tones with a negative Rinne test in both ears, and with prolonged bone conduction. Both drum membranes showed moderate thickening, and one of them showed diminution of luster but no retraction. The diagnosis of otosclerosis was made in spite of the drum membrane changes because of the progressive nature and insidious onset of the defect, without attacks of acute tubal occlusion and not benefited by inflations of the ears.

The other daughter whom I examined had noticed some difficulty in hearing as long as she could remember, but for the past fifteen years this had been progressive. At the age of 37 she was moderately deaf with elevation of the lower tone limit, prolonged bone conduction and negative Rinne test. Both drum

Fig 1—Nora and Elizabeth at the age of 5 years

membranes were quite normal, with a distinct pink glow from the right promontory. The diagnosis was otosclerosis.

The third daughter was not examined but also suffered from progressive deafness. The father died at the age of 58 only slightly deaf, but his trouble had begun insidiously in the forties and had been progressive. A maternal aunt was moderately deaf at the age of 58 and used an earphone. Presumably these three people also had otosclerosis, but without an examination one cannot be certain of this.

The twins, Nora and Elizabeth, aged 41, were the eldest of the five daughters. The twins grew up together, shared the same room, enjoyed equally good health, and had the same illnesses (measles, mumps and whooping cough) at the same time. At the age of 14 both had measles and following this illness Nora noticed a slight defect in hearing which her twin sister Elizabeth did not have. Nora's defect gradually increased, especially over a period of six months at the age of 30, so that she was very much deafer at 41, at the time of examination, than her sister. Elizabeth first began to notice a slight impairment in hearing in one ear (the left) at the age of 30 and this had increased slightly while the hearing in the right ear had remained apparently normal.

² Albrecht W. *Ztschr f Hals, Nasen und Ohrenh* 29: 55-60, 1932.

³ Rodin F. H. *Identical Hearing Defect in Identical Twins* *Arch Otol* 17: 179 (Feb.) 1933.

Examination revealed no abnormality of the nose throat or sinuses of either twin. Both drum membranes of both twins were normal, but in Nora's case a distinct pinkish glow from the region of the promontory was visible. Both had had their tonsils removed, and the tonsil fossae were free from lymphoid tissue. Nora showed a marked defect in hearing, being unable to hear the whispered voice in either ear and unable to hear any of the low pitched forks up to and including c (128 double

head colds, Elizabeth had never been subject to colds. Both sisters noticed that during head colds their hearing was temporarily worse.

From this single observation it appears that frequent head colds have an accelerating or activating effect on otosclerotic foci already present as the result of a hereditary anlage.

2 The second set of identical twins were sisters, aged 52. The family history of deafness was negative except for a paternal uncle who was quite deaf at 35, and his son, who had progressive deafness beginning at the age of 20.

The twins, Antoinette and Hester grew up together in the same environment and had measles, whooping cough and chickenpox at the same time as children. Both were married, but Antoinette was never pregnant while Hester had one child at the age of 33. At the age of 40 Antoinette began to notice gradual loss of hearing with tinnitus. The defect was progressive and not altered by inflations. At the age of 45 Hester first noticed the gradual onset of progressive deafness soon after the menopause. Her defect had progressed more rapidly than her sister's, so that at 52 at the time of the examination, she was the deaffer of the two.

Examination revealed the nose and nasopharynx normal in both. Antoinette had had her tonsils removed seven years before. Hester still had her tonsils which showed only slight evidence of chronic tonsillitis consisting of slight injection and slight enlargement. The drum membranes were normal in Hester except for very slight scarring in one ear, while Antoinette's drum membranes were both slightly scarred but otherwise normal with a suggestion of a pinkish glow from the promontories.

Hester the deaffer of the pair heard the whispered voice close to the left ear not at all on the right. The C₁ fork (32 double vibrations) was not heard in either ear, the C fork (64 double vibrations) was much shortened in the right ear and not heard in the left. The Rinne test was negative in both ears and bone conduction was prolonged (fig 2).

Antoinette heard the whispered voice at 3 feet in the right ear, not at all in the left. The C₁ fork (32 double vibrations) was not heard in either ear, the C fork (64 double vibrations) was moderately shortened in the right ear and not heard in the left. The Rinne test was negative in both ears and bone conduction was prolonged (fig 3).

The diagnosis was otosclerosis with stapes fixation in both twins. In the one the defect came on five years earlier than in the other but had not progressed as rapidly, so that twelve years later the degree of deafness was similar in the two.

Fig 3—Audiogram of Antoinette's hearing solid line right ear broken line left ear. The hearing curves are distinctly different from this patient's twin sister.

What differences can be found in their histories to account for this difference in the development of deafness? Both twins had always enjoyed excellent health. Their menstrual histories were similar except that the menopause came on at 42 in Antoinette compared to 45 in Hester while Antoinette had never been pregnant and Hester had had one child at 33. Antoinette, the first to lose her hearing had always been subject to

Fig 2—Audiogram of Hester's hearing solid line right ear broken line left ear.

vibrations). The Rinne test was negative the bone conduction prolonged. The diagnosis was otosclerosis with stapes fixation. Elizabeth showed a moderate defect in the left ear, whisper being heard only close to the ear while in the right ear whisper was heard at 6 feet. She was unable to hear the C₁ fork (32 double vibrations) in the left ear and this was moderately shortened in the right ear while the C fork (64 double vibrations) was scarcely heard in the left ear and only slightly shortened in the right. Bone conduction was prolonged and the Rinne test was negative in the left shortened positive in the right. The diagnosis was otosclerosis with beginning stapes fixation.

There should be no dispute as to this diagnosis, even by those who are unwilling to make a diagnosis of otosclerosis without a family history, for both parents and all the siblings suffered from progressive deafness.

Here then is a pair of identical twins both suffering from classical otosclerosis, in whom the onset and development of the hearing defect were not identical but strikingly different. In the one the loss of hearing began at 14 and at 41 is quite marked in both ears while in the other the onset of deafness was at 30, and at 41 there is a moderate defect in one ear but only a slight beginning defect in the other ear. What factors present in one twin and absent in the other might be responsible for this difference?

The environment was the same for the two until the age of 33 when Elizabeth married, but by this time there was already a marked difference in the hearing. The menstrual histories were identical and there were no pregnancies. Nora (with the poorer hearing) had always had excellent teeth while her sister Elizabeth had had numerous fillings and had developed pyorrhea. This suggests a difference in calcium and phosphorus metabolism, but the one with the evidence of deficiency was the one with the better hearing. The one definite and striking difference in health between the twins was in the tendency to head colds. Nora had always been subject to very frequent and very severe head colds until the age of 33, when she had pneumonia. Since then her colds had been infrequent and mild. Moreover, these colds were particularly severe and frequent at the age of 30 when her deafness had been most rapidly progressive, while during the past eight years, with very few colds, her deafness had increased but little. Contrasted to Nora's history of frequent severe

severe frequent head colds two or three times a year while Hester had never had more than one mild head cold a year lasting only a few days. Both had been subject to sore throats and tonsillitis when younger, but only Antoinette had had her tonsils removed seven years before. Both noticed that the hearing was temporarily worse with head colds or sore throats

Fig. 4—Audiogram of Sylvia's hearing: solid line right ear broken line left ear

In this set of identical twins with otosclerosis the difference in the onset and development of deafness is not very striking but the earlier onset of deafness in Antoinette corresponds to her frequent severe head colds. Both twins gave a history of tonsil infections in childhood and early adult life but only Antoinette had had her tonsils removed. Might the slower progress of her defect be the result of the tonsillectomy, so that in spite of the earlier onset she now has the better hearing? Since the difference in these twins was not marked, one can only say that the evidence in this case is suggestive that more frequent head colds led to the earlier appearance of deafness in one.

3 The third set of identical twins were sisters aged 25. There was no family history of deafness. Sylvia and Lillian grew up together and both had measles, whooping cough and chickenpox, and both had their tonsils removed as small children. Sylvia first began to notice difficulty in hearing at the age of 17 and this had gradually progressed until at 25 at the time of the examination, she could hear a whisper only at 6 inches in both ears. The C₁ (32 double vibrations) and C (64 double vibrations) forks were not heard in either ear; the Rinne test was negative and bone conduction was prolonged (fig. 4). The left drum membrane was entirely normal, the right was normal except for slightly diminished luster. A pinkish glow was visible from the right promontory. The diagnosis was otosclerosis with stapes fixation.

Lillian did not begin to lose her hearing until 22, but during the past six months, since she became pregnant, this had become considerably worse, so that at the time of examination she could hear a whisper only close to the left ear and at 1 foot from the right ear. The C₁ and C (32 and 64 double vibrations) forks were not heard in either ear; the Rinne test was negative in both ears and bone conduction was prolonged (fig. 5). The right drum membrane was normal with a slight pinkish glow from the promontory, the left drum membrane was normal except for slight thickening and slight loss of luster. The diagnosis was otosclerosis.

Searching for a possible etiologic factor responsible for the earlier onset of deafness in Sylvia, one finds that she had never been as strong as her twin sister and she had always been underweight and particularly susceptible to frequent, severe head colds and sore throats until the past two years, when she has been stronger, has gained weight and has had only one mild head cold each year. Her hearing was always much worse during a head cold. Lillian had never been subject to colds

and when she did have a cold it was mild. She was married at about the time she first began to notice defective hearing, two and a half years ago. She was six months pregnant at the time of examination and since the second month of this pregnancy the hearing had decreased rapidly.

In this third set of identical twins with otosclerosis there was a definite difference in the age of onset of the clinical symptoms. Again there was a marked difference in the susceptibility to head colds, the one who is having many colds becoming deaf first. This further confirms the observation that head colds may constitute an extrinsic controllable factor having an accelerating effect on otosclerosis. It is very interesting that the other previously known extrinsic factor, namely pregnancy, served to accelerate the defect in the twin who did not have head colds, so that her hearing is now as bad as her sister's.

COMMENT

If the premise were strictly correct that the hereditaryanlage is exactly equal in a pair of identical twins then one could say with assurance that there are external influences which can affect the age of onset and rate of progress of clinical otosclerosis and this would be saying a great deal. However, there is one disturbing fact that must be taken into account and that is that identical twins develop from the same egg but from different halves of the egg, and their hereditary environment may differ slightly just as the two halves of any person are slightly different. Thus, otosclerosis often begins first in one ear and may occasionally become very advanced in this ear before the onset of progressive deafness in the opposite ear. The difference in the twins may correspond only to the difference in the two ears of any one with otosclerosis. This detracts considerably from the strength of the conclusions. However, the fact that the lesion developed first in every instance, in the twin who was much more susceptible to head colds is at least suggestive evidence that head colds are an activating influence on otosclerosis. Moreover this harmonizes with a clinical observation made many times before, that a large proportion of persons with otosclerosis complain of an increase in

Fig. 5—Audiogram of Lillian's hearing: solid line right ear broken line left ear. Note difference in hearing curves from this patient's twin sister.

their defect during head colds, though usually this increase is only temporary. In the first set reported Loras' hearing defect advanced relatively rapidly during a period filled with many severe head colds; while subsequently, with relative freedom from colds, the process became inactive and stationary.

It can be concluded, on the basis of the observation in identical twins that head colds apparently have a

activating influence on otosclerosis similar to the influence of pregnancy. This conclusion coincides with clinical experience in the majority of patients with otosclerosis. The mechanism of this effect is not known. It does not seem to be due to direct extension of inflammation through the eustachian tubes though this possibility must be considered. Certainly there has not in my experience, been a demonstrable acute tubal occlusion or tubal catarrh that could be benefited by local treatments. The effect may be entirely systemic, by blood stream transmission of toxins. Further observation of otosclerosis in identical twins will confirm or refute these conclusions. Meanwhile, one can feel justified in any reasonable measures to reduce the susceptibility to head colds in persons with otosclerosis.

Bezold advised repeated hearing tests every six months on patients with otosclerosis to ease the mind of the patient who usually suffers from the impression that he perceives progress of the deafness. He further advised reassurances that the disease rarely leads to profound deafness within a few years but that on the other hand a large number of cases become stationary.

In this manner you have done them much more good than if you try to deceive yourself and them as to their future by a series of attempts at treatment extended over a long time. To Bezold's advice I can add that every reasonable effort should be made to decrease head colds in those persons with otosclerosis who are subject to them.

SUMMARY

Otosclerosis in identical twins offers a unique opportunity to study the etiology of this common disease. This comparatively rare occurrence has been observed a total of five times. Twice the disease ran an identical course in each twin. Twice the disease began five years earlier in the twin who was more susceptible to head colds. Once the deafness began sixteen years earlier in one twin and here the most likely cause for the striking difference was the much greater susceptibility to head colds, and further the progress of the deafness in this patient was most rapid at a time when she was having many colds and was much slower when she became less susceptible to colds.

122 South Michigan Avenue

English Sweating Sickness—After the battle of Bosworth in which Henry VII gained the ascendancy in England, there broke out in the ranks of the conquering army a disease that completely put a stop to the procession of the victorious troops. With disbanded soldiers it was carried into London. The speed of spread can be estimated from the fact that the sickness reached its height in London by September 21, the battle of Bosworth having been fought on August 22. It spread over England rapidly from east to west carried far and wide by the men scattered from the army. In London it killed, within the first week, two lord mayors and six aldermen. It attacked the young and robust, this being one of the points in which it was similar to the Picardy Sweat of which we shall have something to say presently. The mortality of this English sweating sickness was such, according to Holinshed, that 'scarce one amongst an hundred that sickened did escape with life for all in manner as soone as the sweate tooke them or in a short time after yielded up the ghost'. The coronation of Henry was postponed. In Oxford, where Thomas Linacre—who later founded the College of Physicians—was then a student it was so severe that professors and students fled the university which was closed for six weeks. This first outbreak remained entirely in England not even spreading to Scotland or Ireland—Zinsser, Hans Rats, Lice and History, Boston Little Brown & Co 1935.

STREPTOCOCCIC INFECTION SIMULATING RINGWORM OF THE HANDS AND FEET

JAMES H MITCHELL, MD
CHICAGO

Prior to the appearance of our paper¹ on ringworm of the hands and feet, the acrodermatoses were usually diagnosed in this country as eczema or dysidrosis. Subsequently, as a result of that paper and of the innumerable papers that have appeared in the medical and lay press since then, physicians and laymen alike have become so ringworm conscious that practically all dermatoses of the extremities are classed as mycotic. So sure are the medical men of their diagnoses that neither a microscopic examination nor a culture is considered necessary to establish the diagnosis. Widespread areas of dermatitis of external origin are likewise considered to be mycotic and are treated as such, with resultant irritation and continuation of the dermatitis.

In 1928 I² called attention to the necessity of differentiation of mycotic from nonmycotic lesions. A series of cases was reported presenting lesions that suggested, in appearance the epidermophytoses. No fungus could be demonstrated, however either with the microscope or with the culture tube. External irritants in some, and staphylococci in others were thought to be the etiologic factors in these cases. In 1930 Lehmann³ reported a series of cases of vesicular eruptions on the hands and feet due to various causes. He was convinced that, regardless of the etiology of the lesions, internal disturbances were of prime importance. Last year Andrews, Birkman and Kelly⁴ reported a series of fifteen cases of recalcitrant pustular lesions of the palms and soles secondary to focal infection.

Streptococci as a cause of palmar and plantar lesions have not attracted much attention. In 1926 McGlasson⁵ reported a series of fifteen recurrent erysipelas cases as a result of streptococcal infection of the legs complicating mycotic infection of the feet. In 1932 Homans,⁶ a surgeon reported a series of five cases of streptococcal lymphangitis and cellulitis secondary to epidermophytosis or 'athlete's foot'. He makes no mention of microscopic examination for fungi in these cases. Milhan and Katchoura⁷ report a case of small spored trichophyton infection, which was complicated by a streptococcal lymphangitis and axillary adenopathy. Barber⁸ says that 'streptococcal fissures between the toes are usually secondary to epidermophytosis. They may cause recurrent attacks of lymphangitis of the feet, ankles and legs, the origin of which is often overlooked'. In my own experience this has rarely occurred. I have often wondered why streptococcal infections have not taken place in the ruptured vesicles so commonly encountered in acute epidermophytosis.

Read before the Section on Dermatology and Syphilology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 13, 1934.

Perhaps Sabouraud⁹ has given the reason when he says, in effect, that the streptococcus is never a primary or secondary invader as is the ubiquitous staphylococcus. If the streptococcus is present it is there for business and not as an innocent bystander.

In reporting this small group of only five cases I do not wish to become controversial. Some undoubtedly, in looking at the illustrations will say at once that the lesions are those of impetigo which of course they are.

Fig. 1 (case 1)—Impetiginous erosions on sides of feet. There were vesicular lesions on the soles resembling ringworm vesicles.

My object in calling attention to these cases is to make a plea for the use of the microscope and of the culture tube in order that streptococcal infection, which subsequently may be the cause of death, shall not be mistaken for the relatively harmless epidermophytoses and treated as such.

The etiology of impetigo still seems to be misunderstood in America. Sabouraud¹⁰ says that Unna and Schwenter-Trachsler¹¹ wrote a book about impetigo without ever having discovered the cause. He says, further, that there is only one impetigo and that that is streptococcal in origin. It is interesting to find that in the latest editions of three English works on dermatology the authors are entirely in accord with the opinion of Sabouraud, whereas in the latest editions of four American works the authors have the erroneous impression that the cause of impetigo may be either the streptococcus or the staphylococcus. Macleod¹² says "Impetigo contagiosa (Tilbury Fox) is the direct result of the inoculation and presence in the superficial layers of the epidermis of the *Streptococcus pyogenes*. The organism may be obtained in pure culture from the serum of a superficial vesicle, provided a suitable technic be employed." Roxburgh¹³ says "Impetigo is

a streptococcal infection of the superficial layers of the epidermis resulting in the formation of vesicles which rupture readily, the serum, continuing to exude, then dries up into semitranslucent crusts." Walker¹⁴ says "The disease is caused by streptococcus, and that organism may be obtained in pure culture from the early vesicles in a very large proportion of the cases. In the crusts the staphylococci are abundantly present and streptococci are only occasionally found."

Ormsby¹⁵ on the other hand, says "The disease is a pus infection, the result of the transmission to the skin, through the medium of the finger nail, filth or otherwise, of an infection of streptococci, staphylococci, or both." Sutton¹⁶ says "Both staphylococci and streptococci have been recovered from the lesions. It is probable that the staphylococcus is the etiologic factor in some cases of the disorder and the streptococcus in others (probably the majority)." Pusey¹⁷ says "The studies of Crocker, Bockhart, Gilchrist, C. J. White, Corlett and others have established the fact that impetigo may be produced by either the common streptococci or staphylococci. It is most frequently produced by both." Andrews¹⁸ says "This is a superficial staphylococcus or streptococcus inflammation of the skin characterized by discrete thin-walled vesicles and bullae which rapidly become pustular and dry, forming loosely adherent golden crusts."

The explanation of this confusion as to etiology lies in the fact that, first the staphylococcus is ubiquitous and a secondary invader, whereas, the streptococcus is neither ubiquitous nor a secondary invader, and,

Fig. 2 (case 1)—Chains of streptococci in smears of the serous fluid (Zeiss 1/12—Homal IV).

secondly, the staphylococcus invariably overgrows the streptococcus unless, as Macleod¹² says, "a suitable technic be employed." Sabouraud has devised several

⁹ Sabouraud R. *Pyodermites et eczemas*. Paris: Masson & Cie 1928, p. 135. En soi les moeurs de streptocoque semblent assez particulieres. Dans une lesion polymicrobienne staphylo et streptocoque on peut presque assurer d'avance que c'est le streptocoque qui a commence car il est difficile de trouver un cas ou le streptocoque soit venu se surajouter au staphylocoque. Le streptocoque n'est vraiment le second d'aucun alors que le staphylocoque peut etre le second de tous.

Mais tout au contraire dans les cas de parasitisme animal qu'il s'agisse de gale ou de pediculose, presque toujours le streptocoque est le premier qui surviendra. L'impetigo scabieux ou pediculaire revet alors une physiologie speciale parce que ses localisations seront celles de l'affection a laquelle il vient s'ajouter. (The behavior of streptococci appears to be very specific. In a polymicrobial lesion containing both staphylococci and streptococci one can be fairly certain in advance that it is the streptococcus which has been the primary invader, because it is difficult to find a case in which the streptococcus has been secondary to the staphylococcus. The streptococcus is never really secondary to any other organism whereas the staphylococcus may be secondary to all.)

But on the contrary in animal parasitism such as scabies or pediculosis almost always the streptococcus is the first to arrive. Impetigo of scabies or of pediculosis therefore presents a special picture because the localizations will be those of the disorders to which it is joined.)

methods for the culture of streptococci in the presence of staphylococci. One consists in long strokes of the loop over the agar surface without recharging. At the beginning of the stroke nothing but staphylococcus will be found to grow, whereas at the other end the delicate streptococcus will have an opportunity to develop. Another method consists in the use of crystal violet as

Fig. 3 (case 2)—Impetiginous lesions on the hands. The crusts were preceded by vesicles.

a restraining agent for the staphylococcus. Still another consists in drawing up the serum in a Wright pipet, sealing off and incubating it for seventeen hours. In the tip of the pipet the staphylococcus will not survive the partial anaerobic condition, whereas the streptococcus will, and the first drop from the pipet will be an almost pure culture of streptococcus.

Fig. 4 (case 2)—Original twenty-four hour brain broth culture (Zeiss 1/12—Homal IV).

difficulty in growing streptococci, when found in the vesicle smear, by means of the brain-broth liquid medium.

The behavior of the staphylococcus as a skin invader is entirely different from that of the streptococcus. The habitat of the former is the hair follicle, where it may always be found waiting in the follicular vestibule,

ready to step in at the slightest opportunity, such as that presented by friction or epilation, to exercise its pathogenicity. It is a creamy pus, abscess producer or, if sufficiently virulent, a necrosing core producer. The so-called impetigo of Bockhart is not impetigo but a staphylococcic ostiofolliculitis and is characterized by the formation of a small, superficial lake of creamy pus in the follicular orifice. It frequently coexists with streptococcic impetigo.¹⁹

The streptococcus, according to Sabouraud, never invades the hair follicle. On the skin it produces a superficial epidermal vesicle, which, before rupture, contains thick, clear, serous fluid, almost free from pus cells but filled with chains of streptococci. As the very superficial vesicle ruptures, the serous fluid continues to be poured out and forms the "stuck-on" crust. Later ecthymatous ulceration may be produced. The organism is an epithelial (impetigo), endothelial (lymphangitis, endocarditis) and mucous membrane ("septic sore throat") pathogen.

The first case to attract my attention occurred in my private practice, May 25, 1933. A matron, aged 19, who had returned several weeks previously from a honeymoon in Bermuda, appeared with lesions on the feet of such severity that she was scarcely able to walk. She had been treated with continuous wet dressings by

Fig. 5 (case 3)—Vesicular lesions on the side and in the fourth interspace of the left foot.

a more than competent dermatologist for three or four weeks for ringworm, with no success. The patient, the dermatologist and the referring physician agreed that the condition was rapidly becoming worse and that other advice should be sought. According to the patient, however, the diagnosis had remained unchanged. When first seen the conspicuous features of the lesions were the superficial character of the vesicles and the subsequent erosions, which were bathed in a profuse, clear, serous fluid. Microscopically, typical chains of streptococci could be seen in all fields. The brain-broth culture disclosed long chains of hemolytic streptococci. Treatment consisting of aqueous solution of corrosive mercuric chloride and ammoniated mercury ointment healed the infection in one week, without recurrence. No fungus could be found.

The next case was that of a woman, aged 37, who was seen, June 12, 1933, with lesions that had been present on the hands for some weeks. These had begun as small vesicles, which were supposed to be mycotic and had been treated as such with no success by the

¹⁹ Darier. Précis de dermatologie. Paris: Masson et Cie 1928, p. 205.

family physician. The older and larger lesions were impetiginous, with small solitary vesicles containing clear thick, serous fluid. These were grouped, small, superficial vesicles about the fingers of the right hand, but no typical deep-seated vesicles were present. In the smears were found chains of cocci and in the brain-broth cultures hemolytic streptococci. With twice daily

baths of corrosive mercuric chloride and ammoniated mercury ointment the hands were healed as shown in figure 3 taken one week later. No fungus could be found.

After seeing these two cases I began making routine examinations and cultures for streptococci, and on July 24 I found another case which more closely simulated a fungous infection than any of the four other cases. The patient was a high school girl aged 15 years who had been swimming in the lake. The lesions had first appeared several weeks before in the fourth interspace of the left foot. They next appeared on the ball of the foot and lastly on the outer margin of the foot. The microscopic pictures of the smears and of the

Fig. 6 (case 3)—Vesicular lesions on the sole of the same foot as in figure 5

brain-broth cultures are similar to those of the other cases. Aqueous solution of corrosive mercuric chloride and ammoniated mercury ointment brought about a condition of healing, as shown in figures 5 and 6, taken one week later.

Having seen these three cases I began a constant watch for similar cases, as I was inclined to the belief that I had been overlooking similar cases in the past. Not until April 20, 1934, however, did I find the fourth case of this group. The patient was a college student, aged 21, who lives in a city 400 miles from Chicago. He gave a history of having had dermatitis on the hands more or less continuously for the past year and a half. During that time he had been given three or four roentgen treatments with considerable relief. During the preceding month, however, there had developed severe vesicular and crusted lesions on the hands. Two weeks later, swelling and tenderness developed in the left axilla. There had been much ringworm in the school, and the condition was thought to be mycotic. The patient finally came to the city to consult Dr. Nelson Percy, who in turn referred him to me. At the time of observation there were numerous small superficial vesicles and small yellow crusts. At the base of the dorsum of the right hand was a typical "stuck-on" crust of streptococcic impetigo. The toes were free except for suggestive exfoliation in the right fourth interspace. No fungus could be demonstrated by microscope or by culture. Chains of cocci could be found in all fields with small groups of cocci here and there. The culture contained long chains of hemolytic streptococci slightly

contaminated with hemolytic staphylococci. Treatment consisted of corrosive mercuric chloride soaks daily for one week. At the end of that time the condition was practically healed. Owing to the preexisting dermatitis he was advised to discontinue the mercurial baths and to begin daily baths of potassium permanganate. A letter ten days later reported that the hands were entirely clear.

The fifth patient was a girl aged 15 years, who had been treated for ringworm of the right palm for several weeks. Despite much attention and constant treatment with "ringworm salve," the condition had continued to grow worse. During the week preceding the consultation, which occurred May 23, 1934, some pain and considerable tenderness in the hand had developed. There was also some tenderness, but no redness, along the ulnar side of the flexor surface of the forearm. There were numerous "stuck-on" scrous crusts, which had been removed before the photograph (fig. 10) was made. There were also numerous vesicles, the superficial character of which can be seen on the side of the middle finger. All the vesicles were carefully opened and treatment with corrosive mercuric chloride soaks begun. No fungus could be found. The healing was reported as rapid and uneventful.

SUMMARY

There is a marked tendency to regard all acrodermatoses as ringworm of the extremities.

There is a need for careful laboratory examination of all dermatoses of the hands and feet before arriving at a diagnosis.

Fig. 7 (case 3)—Original brain broth culture (Zeiss 1/12—Homal IV)

I agree with Sabouraud, Macleod, Walker and Roxburgh that impetigo (Tilbury Fox) is due to the streptococcus, this fact can be proved with ease.

A group of five cases of streptococcic infections (impetigo) of the extremities simulated mycotic infection sufficiently to lead to errors in diagnosis.

The infections were found to yield within one week to baths of corrosive mercuric chloride and weak ammoniated mercury ointment.

ABSTRACT OF DISCUSSION

DR GEORGE C. ANDREWS, New York. The paper of Dr Mitchell is valuable because it throws light on a condition that has not been recognized. It also shows the importance of studying bacteriologically unusual and atypical cases and the importance of not classifying them as eczema or pustular psoriasis or dermatophytosis without adequate reason. In my study of pustular eruptions of the hands and feet that resem-

Fig 8 (case 4)—Impetiginous lesions on the fingers and right wrist

bled pustular psoriasis but were due to tonsillar infections. I ran across a case similar to Dr Mitchell's. This patient presented pustular and vesicular lesions mostly pustular on both palms and soles. There were no lesions between the toes. The cultures and microscopic examinations for fungi were negative. There were no characteristic lesions or any history of psoriasis. The patient said that she had arthritis for six years and infected tonsils. Her hands and feet had been involved for four years and the clinical appearance was somewhat like the lesions on the foot in the picture Dr Mitchell presented except that they were mostly pustular. Microscopic examinations of cultures from the hands in all instances showed *Streptococcus viridans* much to my great surprise. There were three cultures taken and each of the three showed *Streptococcus viridans* and nothing else. This woman has very large diseased tonsils and she has been told that they should come out. Her reaction to streptococcus toxin vaccine is very strong, in other words, she is apparently allergic to the streptococcus. So far there have been to my knowledge about twenty-four cases which clinically resemble pustular psoriasis of the hands and feet with sterile cultures but no other signs of

Fig 9 (case 4)—Brain broth culture (Zeiss 1/12—Homal IV)

psoriasis and these patients all had focal infections. Of these nine have been cured by the removal of the tonsils or the focal infections. I think that there are cases resembling pustular psoriasis which also show streptococci in culture from the lesions on the hands and feet as well as cases of ringworm.

DR ERWIN P. ZEISLER, Chicago. I should like to call Dr Mitchell's attention to the work published four years ago by Jordan of Jadassohn's clinic on the occurrence of streptococci in normal skin. Up to this time a number of observers had reported finding streptococci in approximately 15 per cent

of cases from the normal skin. Dr Jordan reports a series of 150 cases in which cultures were taken of scrapings from the skin with a sterile scalpel from different parts of the body—all normal individuals with no skin lesions and no history of impetigo. Cultures were made on crystal violet bouillon and on ascitic fluid with 1 per cent grape-sugar bouillon. In 148 of 150 cases he reported the positive finding of the streptococcus. I should like to ask Dr Mitchell how he explains the correlation of these observations with his report here of the streptococcus in these lesions.

DR MARION B. SULZBERGER, New York. Dr Mitchell has brought out a point of great importance that there is a tendency to jump at the diagnosis of dermatophytosis and dermatophytid in all eczematous vesicular scaly crusting hand and foot eruptions. I would not today have made the clinical diagnosis of dermatophytid, as far as one can judge by the appearance in a photograph in a single one of the cases which Dr Mitchell has thrown on the screen. The question of whether such cases are primary infections is one that must be decided. This would differentiate them from dermatophytid in which one does not find the organism as a rule. It is well known that there can be primary infections of the hands and feet with organisms other than fungi. Dr Zeisler brought up a point that I wish to stress emphatically. I was in Breslau at the time Jordan made these cultures of streptococci. From Jordan's work and from subsequent observations, one is forced

Fig 10 (case 5)—Vesicular and crusted lesions on the right hand

to the conclusion that the finding of streptococci in skin lesions does not mean that lesions are to be attributed to streptococci. This introduces a dilemma in the question of the etiologic significance of an organism found in a skin lesion. Streptococci, staphylococci, *Monilia* organisms and in this country probably also organisms of the *Trichophyton* group are ubiquitous and can be found in practically all skins and in practically all skin lesions if sufficiently delicate methods of culture are used. The finding of these organisms is no proof of their causal role. Therefore as Dr Mitchell has been hand and footing it about the country for the last year in the bacteriologic and mycologic investigation of these cases others have been following him about more or less figuratively with syringes with bacterial extracts in order to find out whether one could tell by the skin reactions and the immunologic status of these patients which organisms were responsible for the hand and foot lesions. Unfortunately that is not the case. However I think that there may be another immunologic way of finding out which organisms are responsible for these lesions and that is by the therapeutic effect of specific desensitization. In a certain percentage of cases of presumable dermatophytids one gets remarkably good therapeutic effects with desensitization treatment with *Trichophyton* extracts. In other cases one is forced to employ *Monilia* extracts. In many others neither of these desensitizations help. I have been trying to work up to a polyvalent extract which will include staphylococci and streptococci eventually and to attempt to desensitize this group of cases provided they are refractory to other therapy by this means.

DR JOHN G. DOWNING Boston About a year ago after being constantly confronted with statements that the persistence of prolonged industrial dermatitis cases was due to a secondary fungus infection I started taking cultures of these persistent cases, employing an expert mycologist for the work. We found no fungi of a pathogenic species in these persistent dermatoses but found plenty of streptococcus organisms. The fungi that we found corresponded to those that we found in studies of the normal skin and the streptococci corresponded in some details, with the difference that those on the normal skin were never of the *Streptococcus hemolyticus* strain.

DR JAMES HERBERT MITCHELL Chicago I am familiar with the work on streptococci in normal skin. There are several papers on the subject in the French literature. I am familiar with those but I didn't think it necessary to mention them as I am dealing with a pathogenic *Streptococcus hemolyticus* and not with a saprophytic streptococcus. Having found *Streptococcus hemolyticus* in a few cases I began to fear I was overlooking the organism in other cases. I had an expert bacteriologist trying to find streptococci in cases in which they did not exist, and at times I was impatient because the organisms were not found. The hemolytic streptococcus is not ubiquitous and is not an innocent bystander. I am merely presenting these cases for your consideration. I agree with Dr Sulzberger that with one exception I didn't regard the cases as mycotic eruptions but five other physicians and dermatologists did regard them as ringworm. That is the point I am trying to make. I don't say that they were not justified in doing so. In my experience neither serum nor anything else is needed because the lesions clear in one week with mercuric chloride baths and ammoniated mercury salves. In regard to the statements Dr Downing made all of these organisms are *Streptococcus hemolyticus*. They may have been just hanging around there as guests but in my opinion they were having something to do with the process.

Clinical Notes, Suggestions and New Instruments

A CASE OF PETROSITIS WITH SURGICAL DRAINAGE AND RECOVERY

KARL W. GRUPPE, M.D., UTICA, N. Y.

In the last few years, medical journals have been presenting increasing numbers of reports of research and clinical work on the complication of mastoiditis known as petrositis, or involvement of the apex of the petrous pyramid. This complication hardly recognized prior to the work of Gradenigo¹ reported in 1904 is now receiving the attention it deserves. Diagnostic measures in which history, physical examination and roentgen studies² all play major parts have been established and various surgical approaches aimed at drainage of this remote region have been devised and tested. In the future, then a lessening in the incidence of meningitis, brain abscess and chronic otorrhea from this cause may be anticipated only so far as otologists and general practitioners who are often the first to see these cases, will familiarize themselves with the disease and the significant points in its diagnosis.

My object in this paper is to present a case illustrating the complication in question. The symptoms, physical signs and roentgen observations were definite and conform to the established pattern to which unfortunately, not all cases do.

REPORT OF CASE

J. S., a Polish woman aged 38 was referred to me by Dr Charles Greene of Utica April 28, 1934. The story was one of gradual onset of left sided earache following a mild head cold. Discomfort increased and on the third day before and was sought was associated with mastoid pain. No generalized headache, eye pain, vertigo, chills or fever were complained of. The past history revealed nothing of general or local interest.

Examination, April 28, revealed a temperature of 99 F. The left ear drum was red and bulging and intact. No canal wall sag was present but the mastoid tip and antral regions were definitely tender. There were no meningeal signs. Extraocular movements were normal as well as the optic disks. The nose, sinuses, throat and right ear were normal.

A left myringotomy was done, releasing considerable thick pus. The patient was then observed carefully and on the following day was somewhat improved. On the second day, however, the mastoid pain became worse and headache and pain behind and around the left eye were complained of. The temperature rose to 99.8. She was admitted to St. Luke's Hospital April 30, with a tentative diagnosis of mastoiditis with petrous apex involvement, and a simple mastoidectomy was done. The mastoid was very cellular and large and seemed involved by a hemorrhagic process with here and there frank pus pocketed off. Large areas of middle fossa dura and lateral sinus were exposed and appeared healthy. The medial antral surface was then curetted and while work was being done just above the horizontal semicircular canal a thin stream of pus escaped. The

Petrous apexes showing probe in place in the drainage tract. In the original film definite loss of structure in the left apex is more obvious than in this reproduction.

orifice was then widened and the patient was sent back to the division for observation, the wound being left wide open. Culture showed a hemolytic streptococcus.

For about eighteen hours there was definite improvement in headache and eye pain but on the evening of the second post-operative day severe headache developed and a questionable Kernig sign was elicited. Lumbar puncture at this time showed a pressure of 100 mm of water, a negative Pandy test and a cell count of 6 lymphocytes. For one week varying headache and pain over the fifth nerve distribution continued and the patient complained bitterly of aching upper and lower teeth during the last day of this period. The temperature fluctuated between normal and 100.4 and mild leukocytosis was present. Roentgen examination of the petrous apexes showed pneumatized tips with probable disease on the left. The pleas of the patient for extraction of the aching teeth were ignored and she was returned to the operating room. A Kopetzky-Almour drainage was contemplated in the event that the tract could not be followed. This, however, was not necessary as after dissection had been done down to the superior semicircular canal it was possible to work a probe well out into the tip followed by the release of creamy pus. The posterior buttress was then removed and more of the middle fossa floor up to the posterior

¹ Gradenigo Giuseppe Arch f. Ohrenh. 62:255 1904

² Taylor H. K. Ann. Otol. Rhin. & Laryng. 40:367 (June) 1931

canal wall and the middle fossa dura was then elevated to about two thirds of the way to the tip. No extradural pus was found. Silkworm-gut strands were left in place in the probe tract and the patient was returned to the division for further observation.

Following this procedure no labyrinthine signs were noted and save for a temperature flare to 102 on the second post-operative day at which time lumbar puncture was again negative the course was one of gradual improvement. The tract was probed each day and the discharge lessened. The middle ear likewise started to clear, indicating that there was no secondary fistula through the peritubal cells. May 15 Dr. Kopetzky, then in Utica attending the state convention kindly consented to see the patient and predicted recovery. May 19 Dr. Greene gave a transfusion of 500 cc of blood to combat a secondary anemia. The patient remained afebrile from May 13 until discharge on June 4 and several white counts were normal. Some residual headache was present but easily controlled by acetylsalicylic acid. The wound healed and the middle ear returned to normal and now over an eight month period of observation the headaches have entirely cleared and the patient is gaining and enjoying good health.

COMMENT

The features of this case are characteristic. The eye pain indicating involvement of the first branch of the fifth nerve, and later the involvement of all three branches as evidenced by the aching teeth, is a sign of great importance. This early eye pain along with the finding of a large pneumatized mastoid and the successful search for a fistulous tract confirmed the diagnosis of apex involvement. The type of mastoid structure is of importance since it is almost entirely with these large cellular types that pneumatization of the tip occurs a prerequisite to true coalescent petrositis. Recent anatomic studies have shown that tip pneumatization occurs in about 30 to 40 per cent of this type of structure. Roentgen study simply confirmed the presence of apical cells. The finding of the fistulous tract indicated deep pus under pressure and because of its escape it was considered safe to observe the patient for a time. In this connection there are undoubtedly many cases of apical involvement which, failing to give classic signs or for some reason passing unrecognized drain themselves through the same tract by which they were infected. Some drain adequately and some go on to meningitis, labyrinthitis, brain abscess formation or the less dramatic chronic discharging ear. Sixth nerve paralysis did not occur in this case and does not in perhaps the majority of cases. Facial paralysis often observed, likewise was not present at least to any marked degree although Dr. Kopetzky did feel that a slight paresis was present in this instance.

Operative procedures are of two types the external or subdural approach advocated by Eagleton³ and others and approaches carried out through the petrous bone itself, of which the Kopetzky-Almour⁴ operation has been the most discussed. Frenchner⁵ has advised the approach through the arch of the superior semicircular canal and it was this route through which drainage was established in this case, a route too hazardous unless, as occurred here, some form of tract has been established by nature, indicating soft bony structure. The choice of operation has been the subject of much debate but certainly it is generally conceded that in the presence of a fistulous tract its location should determine at least the first attempt at providing adequate drainage. All procedures are fraught with some danger, but no one is as dangerous to life as the policy of prolonged watchful waiting. One point in favor of drainage through the bone itself is that for some time after apparent clearing a potential tract exists which may function as a safety valve should a flare up of pocketed off material occur. Subjecting the patient to a preliminary radical mastoidectomy should give little concern if it is necessary for the provision of drainage. Its performance precedes the Kopetzky-Almour and Eagleton operations but is held unnecessary by Myerson, Rubin and Gilbert,⁶ who also advocate the subdural approach.

3 Eagleton W. P. *Tr. Am. Laryng. & Otol. Soc.* 1930 p. 338.
4 Kopetzky S. J. and Almour Ralph. *Ann. Otol. Rhin. & Laryng.* 39: 996 (Dec.) 1930. 40: 157 (March) 1931.

6 Myerson, M. C., Rubin H. W. and Gilbert J. G. *Improved Operative Technique for Suppuration of the Petrous Apex Arch. Otolaryng.* 19: 699 (June) 1934.

Petrous apex involvement should be borne in mind and the diagnosis considered in cases giving an acute or chronic ear history and presenting any or all of the following symptoms: generalized headache, fifth nerve pain sixth or seventh nerve palsies, low grade sepsis, labyrinthine irritation, evidence of intracranial complication.

RELATION OF CYSTIC DUCT OBSTRUCTION TO DEPOSITION OF CALCIUM IN THE HUMAN GALLBLADDER

REPORT OF CASE

ELLIOTT C. CUTLER, M.D. AND ROBERT BOGGS, M.D. BOSTON

The relationship of cystic duct obstruction to the deposition of calcium in stones formed within the gallbladder was demonstrated experimentally by Wilkie¹ in 1928 and elaborated on by the clinical studies of Phemister² in 1931. Andrews and Hrdina³ corroborated this observation, both experimentally and clinically, in 1933. Walsh and Ivy⁴ obstructed the cystic duct in four dogs and reported calcium gravel in one post mortem.⁵ These authors reported cases in which the calcium content of the stones was consistently very high and in some cases the content approximated totality.

In the routine study of gallbladders in this clinic the following case was called to our attention and we felt that it merited recording since it seems to represent an earlier stage in the deposition of calcium following cystic duct obstruction than those heretofore reported in which detailed analysis was made of the stones.

REPORT OF CASE

History.—A man aged 54 was admitted to the surgical service with a diagnosis of cholecystitis and cholelithiasis.

For the past fifteen to twenty years the patient had had occasional attacks of vague indigestion with no relation to the food or time cycle. During the past three years the pain had become colicky in character and one month previous to admis-

Fig. 1—A cholecystogram showing ring shadows in body and neck and minute positive shadows in fundus of gallbladder. B enlargement of A.

sion he had a severe attack, which kept him in bed for five days. Except for the last attack, when there was a slight subicteroid tinge there was no jaundice.

From the Surgical Clinic and the Surgical Research Laboratory of the Peter Bent Brigham Hospital.

4 Walsh E. L. and Ivy A. C. *Observations and Etiology of Gallstones*. Ann. Int. Med. 4: 134 (Aug.) 1930.

5 Fellows working in this laboratory have reported in a personal communication the accidental finding of gravel in the gallbladder and kidneys of a dog with no previous treatment that might account for it.

On admission the temperature was 98 F, the pulse 70 and the respiration rate 20. Blood pressure was 120 systolic, 88 diastolic. Physical examination was negative. The abdomen was soft and pliable with no areas of tenderness or rigidity. No palpable organs or masses were felt. The liver border was at the costal margin.

A cholecystogram following oral administration of dye failed to reveal the gallbladder wall. Distributed linearly from the fundus to the neck were several ring shadows approximately 7 mm in diameter. The fundal area was filled with minute positive shadows, none having a greater diameter than 2 mm (fig 1).

Fig 1.—A roentgen appearance of excised gallbladder. Ring shadows are displaced from original positions. B roentgen appearance of contents of excised gallbladder.

Laboratory Examination—The urine was clear, with a specific gravity of 1.018, and was negative for albumin, sugar and bile. Microscopic examination showed epithelial debris.

Examination of the blood showed 4,700,000 red blood cells and 6,000 white blood cells, with 90 per cent hemoglobin. The differential count revealed polymorphonuclear leukocytes, 73 per cent, lymphocytes, 25 per cent, monocytes, 2 per cent, basophils 0 and eosinophils, 0.

Cholecystectomy was performed by one of us (E. C. C.), and the common duct was explored. The convalescence was prolonged by the unfortunate occurrence of a small pulmonary embolus on the sixteenth postoperative day and subsequent edema of the left leg for several weeks but was otherwise uneventful.

Pathologic Report—The gross specimen consisted of a gallbladder measuring 0.8 by 3.8 by 12 cm. The external surface was covered with a delicate layer of serosa and, except for a rare area of fibrosis, was everywhere smooth and glistening. The wall averaged 3 mm in thickness. The mucosa was a light pinkish gray, and no area of erosion could be seen. The lumen contained 50 cc of an extraordinarily tenacious greenish gray mucoid substance. Embedded in this material were nine large spherical white stones. These had a linear distribution extending from the fundus into the neck. The cystic duct was completely obstructed by a reddish yellow stone of similar size. Throughout the fundal portion were scattered many small whitish stones roughly estimated at 200. The larger stones averaged 7 mm in diameter and the smaller ones 2 mm. The cut surfaces of the stones were reddish brown with radiating crystalline markings. The periphery of all the stones with the exception of a few of the smaller stones and the one in the cystic duct, was formed by a very thin layer of chalky white material. Roentgenograms of the excised gallbladder and of

the contents were similar to those taken before operation (fig 2).

Microscopically, the mucosal elements were well preserved. Numerous papillary projections were seen with a moderate amount of fibrosis in these regions. The wall was thickened and there was a moderate cellular infiltration of all the layers.

Chemical Report—Examination of the bile showed calcium 28 mg per hundred cubic centimeters, cholesterol, 750 mg and bile salts, 0.

The large stones showed calcium 36 per cent by weight, bile salts 74 per cent and cholesterol, 89.0 per cent. The small stones showed calcium 24.0 per cent by weight, bile salts 30 per cent and cholesterol, 73.0 per cent.

COMMENT

The importance of cystic duct obstruction on the deposition of calcium has been fairly well established both clinically and experimentally.⁶ Reconstructing our case in the light of recent work, we have apparently a case of chronic gallbladder disease with the formation of cholesterol-pigment stones. The absence of bile pigments is compatible with the views of Andrews and his co-workers⁷ in that the absence of bile salts is an important factor in cholesterol precipitation. Following the formation of stones, one of the larger stones passed into the cystic duct obstructing that orifice and initiating the deposition of calcium, the time apparently coinciding with the onset of clinical symptoms. The recent deposition of calcium is further corroborated by the peripheral distribution and the small amount of calcium within the stones themselves.

CONCLUSIONS

This case further substantiates the theory that obstruction of the cystic duct initiates the deposition of calcium and seems to represent an early stage in that process.

CANCER OF THE TRANSVERSE COLON IN A SEVEN YEAR OLD BOY

DANON B. PFEIFFER, M.D. AND J. K. W. WOOD, M.D.
WILLOW GROVE, PA.

In considering the question of cancer of the colon in children one is dealing with an unusual condition. Although it does occur rather infrequently, one should keep it in mind in the consideration of the diagnosis of some obscure abdominal conditions. The incidence of cancer in persons under the age of 15 years is so low that reported cases are regarded as oddities.¹ Cases of carcinoma of the intestinal tract occurring in young persons must be looked on as extremely uncommon.² In considering the incidence of carcinoma of the large bowel in children Philipp³ stated that 28 per cent of ninety-three cases affected the intestinal tract. In 1914 Redho⁴ was able to find but 536 cases of carcinoma during the period of youth in a review of the literature up to that date. Schamoni⁵ performed 2,500 necropsies on children in the first ten years of life and found not one case of carcinoma. In a review of 831 cases of cancer by Janusz⁶ he recorded only four instances in patients under the age of 20 years. Matzen,⁷ in reporting 8,054 cancer cases from Bavaria, detected but seventeen cases during the first two decades of life. In Odessa, Medwedew⁸ saw 1,181 cases of cancer in twenty-five years of observation but recorded none in children under the age of 10 years. Wainwright⁹ states that, including his case, there are apparently only seven recorded cases of cancer of the colon above the sigmoid in

REPORT OF CASE

History—A boy, aged 7 years had a severe attack of abdominal pain in December 1933 The family physician was called He could find nothing wrong with the child and the pain had ceased This attack of pain lasted about half an hour, there was no vomiting but there was constipation From December

Fig 1—Section through carcinomatous area

until he came under our observation he had attacks of abdominal pain, but as nothing had been found they were not considered of any significance The boy was growing taller but he seemed to be losing weight

When he was brought to the office about 8 p m June 28, 1934, he complained chiefly of swelling of the right testicle His mother said that about three weeks previously he was playing ball with other boys and was hit in the abdomen with

the ball This caused severe pain, which subsided shortly Since that time he had had several attacks of severe abdominal pain lasting a few hours every three or four days There had been no attacks of vomiting That evening when he was getting ready for bed his mother noticed a swelling of the right testicle and then the boy was dressed and brought to the office The bowels had been regular

Fig 2—Gross specimen of polyp and infiltrated area immediately beneath

The temperature was 99.2 F, pulse 80 respiration rate 18 The boy was pale and had a rather apprehensive expression The physical examination of the head was negative The tongue was slightly coated and the tonsils were moderately enlarged and cryptic The neck showed no palpable glands The chest lungs and heart were normal On examination of the abdomen there was no distention and peristalsis was apparently normal There was no area of definite tenderness nor were there any palpable masses The right testicle was swollen to about twice its normal size There were no signs of hernia The extremities were normal

The past medical history showed chickenpox and measles The father and mother were living and well Three other children were living and well One brother aged 3 years, had died eight years before as a result of intestinal obstruction due to Meckel's diverticulum and peritonitis

The patient went to school and was in the proper grade for his age

The impression at that time was that the boy had (1) swelling of the right testicle secondary to the trauma of the accident with the ball (2) an incipient abdominal condition with surgical complications

The mother was advised to take the boy home, put him to bed, elevate the scrotum on a pillow and apply epsom salt as a wet dressing to the testicle She was to give the boy a light diet and if there should be any vomiting, to report immediately A dose of magnesium magma was prescribed to be given in the morning for good elimination

The next morning according to a telephone conversation with the mother the boy was comfortable and the swelling in the testicle had disappeared She was advised to give the boy an enema and keep him in bed another day There was a greenish black bowel movement as a result of the enema

That evening, June 29 about 7 p m, the patient was seen at home as he had vomited some food and he had severe abdominal pain The temperature was 99 F, pulse 76, respiration rate 18 On examination of the abdomen there was no distention no definite tenderness or palpable masses, and the peristalsis was present but not overactive The swelling of the testicle had disappeared It was apparent that the boy did not have appendicitis or a Meckel's diverticulum It was felt that the boy had an obscure surgical condition An ice cap was ordered to be applied to the abdomen and a placebo was prescribed

The next morning the boy was seen about 11 o'clock He had had occasional attacks of abdominal pain and had vomited

¹⁰ Chajutin D M Ztschr f Krebsforsch 29 389 1929
¹¹ Ewing James Personal communication to the authors

several times during the night. There had been four bowel movements since he had been seen the previous evening. These bowel movements were accompanied by considerable mucus but no blood. The temperature was 99.1 F, pulse 84, respiration rate 18. On examination of the abdomen a sausage-shaped mass about 4 inches long by 2 inches wide was palpated in the middle portion of the left side of the abdomen. This mass was slightly tender. The diagnosis was intussusception or a volvulus.

The boy was transferred to the Abington Memorial Hospital in the service of Dr. Pfeiffer who thought the mass might be fecal impaction and another enema was ordered. Good results were obtained and the mass could not be palpated. The boy felt better. The next morning another enema was given and it was effectual. The boy felt much better. The abdomen was soft and tympanitic with no masses and was not tender. The next day a barium sulphate enema was given. The patient was having severe abdominal cramps. The mass was again palpable but this time near the middle of the upper left quadrant. The temperature was 99.3 F.

A roentgen report of the barium sulphate enema showed that it flowed freely from the rectum in the descending colon about 2 inches above the level of the iliac crest. Here the flow was arrested rather abruptly and the colon above could not be made to fill either by change of posture or under the influence of pressure.

Dr. Pfeiffer recommended operation because of the obstruction.

Operation.—A right rectus displacement incision was made. A small amount of clear fluid was present in the abdominal cavity. The mass previously felt was then located and withdrawn through the incision. It was situated in the transverse colon just proximal to its midportion. The distal end of the colon was dilated but empty of fecal matter. The proximal end of the colon was moderately dilated and contained some feces. The lesion itself consisted of a slightly movable mass which was free within the colon but attached to its wall evidently a polyp. It was approximately 1½ inches (3.8 cm.) in diameter. At the base was an evident infiltration of the wall of the colon. The regional mesentery showed a number of small lymph nodes which however seemed translucent and not suggestive of metastasis. The lesion was favorably situated for the Mikulicz procedure and because of the obstruction present this operation was selected. The omentum was separated at a distance from the lesion, the mesentery containing the regional lymph nodes was tied and the entire infected loop with the adherent tissues was brought out through the upper angle of the incision. The wound was closed up to the bowel and the proximal and distal segments of the bowel were severed with cautery between clamps. The wound had previously been protected with petrolatum gauze. Gauze was placed around the bowel and the clamps were enclosed in the dressing. The appendix appeared to be normal. It was not removed. The boy died the next day of alkalosis and failing heart.

The pathologic examination revealed a fibroma showing superficial ulcerations, hemorrhages, extensive round cell infiltration and several fields of misplaced, irregularly enlarged and distended intestinal glands which strongly suggest the presence of adenocarcinoma. The pathologist's diagnosis was fibroma with adenocarcinomatous changes.

CONCLUSIONS

In a case of recurring cramplike pain without any definite cause the question of intestinal obstruction due to cancer should be thought of at any age and proper studies carried out to check the diagnosis.

217 Davisville Road

Distribution of Estrogenic Substance.—A great deal of evidence has accumulated to show that oestrogenic substances are widely distributed throughout the animal, mineral and vegetable kingdom but their main source of supply is the urine of pregnant women (especially during the last half of gestation), the ovaries (follicular fluid) of all mammals and the placenta of women and animals.—Robinson, A. L. and Darrow, M. M. *The Differential Diagnosis of Pregnancy*, *Lancet* 11 (Jan 5) 1935.

Therapeutics

THE THERAPY OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, MD
CHICAGO

NOTE.—In their elaboration, these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics, Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed the series will be published in book form.—Ed.

THERAPY OF ARTERIAL THROMBOSIS OF THE EXTREMITIES

OUTLINE BY DR. G. W. SCULPHAM¹

Even though the essential pathology as well as the etiology of arteriosclerosis obliterans of the extremities and of thrombo-angitis obliterans (affecting chiefly younger persons) are different, the treatment of these two conditions is similar. Applicable in both disorders are the same methods, especially those which attempt to improve the impaired circulation. Diabetic gangrene which is essentially arteriosclerotic gangrene in the patient with diabetes, though it may be also the result of infection, must be differentiated because of the additional systemic treatment required. Intoxications such as lead poisoning and ergotism may result in vascular disease. Polycythemia vera and a less well determined group of infectious diseases result in arterial involvement. These conditions must be treated from an etiologic point of view. Raynaud's disease (qv) falls into the group of functional vasospastic disorders that require separate discussion, the syndrome frequently occurs in scleroderma as well as an idiopathic vascular disease.

Even though involvement of the veins may occur in conjunction with arterial disease and the veins are characteristically involved in thrombo-angitis obliterans, the therapy of vein thrombosis differs from that of artery thrombosis sufficiently to require separate discussion (see therapy of thrombophlebitis).

DIAGNOSIS

The diagnosis of vascular disease should be made as early as possible, as the treatment revolves chiefly around the prevention of necrosis or its greatest possible limitation when it actually makes its appearance. Hence one should take seriously the cramplike pain on walking so severe that the patient must stop (intermittent claudication, intermittent limping, dysbasia angiosclerotica) and due to angiospastic ischemia instead of the necessary reflex dilatation of the working muscle, rather than pass it off as due to flat feet or "rheumatism," as is so frequently done. Such pain may be the precursor of gangrene. It demands investigation of the condition of the blood vessels of the extremity. "Goldflam's test" consists of observing the color of the foot while the recumbent patient raises the extended leg repeatedly. A deathlike pallor of the foot or parts of it is diagnostic. This is likely to be followed by extreme redness when the limb is next permitted to

¹ After a lecture given before the Cook County Hospital Therapeutics Club Nov. 19, 1934.

hang down Pulsations in the arteries in the affected foot may be absent or greatly diminished They are looked for especially in the dorsalis pedis artery (first interosseous space) or in the posterior tibial artery (behind the internal malleolus) Even the pulse in the popliteal artery may be poor Chronic coldness of the extremity or great redness of the extremity when the limb is dependent are also likely to be present Trophic disorders, such as indolent fissures, ulcers or a withered condition of the skin or impaired nutrition of the nails, are highly suggestive So is rest pain Cyanosis and paresthesia or persistent edema announce the imminence of gangrene, the first evidence of which may be one or more hemorrhagic blisters on a hyperemic base Toes or fingers are nearly always first affected Appropriate treatment for prevention of trophic disorders and of gangrene is the all important aim of therapy in cases presenting difficulty in walking, vague pains, and coldness of the feet

PROPHYLAXIS

1 *Causal*—As syphilis may be responsible for vascular disease, investigation for its possible presence and appropriate treatment, if syphilis (q v) is discovered, is of importance The presence of diabetes mellitus requires special therapy (q v) When neither of these conditions is present, one must think of the possibility of focal infection (q v), precipitating or aggravating the conditions, and eliminate infectious foci when found Neurosis (q v) may be responsible for instability of the vasomotor system Tobacco is an important contributory factor to a vasospastic tendency Hence its use must be completely interdicted, as though the patient were anaphylactic to it As there is a possibility that ergotism might play a role in thrombo-angitis obliterans, most especially of the Russian Jew, it might be advisable to forbid the use of rye bread

2 *Circulation*—The demands on the defective circulation should be diminished That exertion is an undoubted predisposing factor is evidenced by the appearance of intermittent claudication and the fact that the condition appears especially in the extremity most used Hence a threatened limb must be put at rest and in such a position as to favor optimal blood perfusion of the extremity Standing or walking must be forbidden, and constricting influences, such as garters or tight shoes, carefully shunned

Exposure to cold may be a determining cause of the onset of gangrene Hence threatened extremities must be carefully protected against chilling In extremely cold weather, a predisposed individual should stay indoors A warm dry climate may prevent a catastrophe

Prevention of traumatism from corns, callosities or ingrowing toe nails is just as necessary for these patients as for the patient with diabetes (See "foot hygiene" of diabetes mellitus) Cutting of corns or callosities must be performed with complete surgical asepsis, as the beginning of serious trouble is often traceable to infection during such manipulations Even the smallest injury requires scrupulous asepsis "The feet should be kept cleaner even than the face" They should be kept dry by means of a sterile dusting powder

TREATMENT

Treatment must take care of cases presenting pain, which may be present with or without lesions, and cases presenting trophic disorders and gangrene

The treatment should always be proportionate to the degree of disturbance, but, if a mistake is made, it should be in the direction of excessive care rather than apathy, to which many a limb has been sacrificed

Pain—As long as the pain of intermittent claudication is relieved by the prophylactic therapy described, it may suffice If it does not, or if pain in the toe or the calf becomes constant and independent of locomotion, it should be interpreted as the "trophoprodromal pain," an indication that trophic lesions and even gangrene are imminent and that thorough treatment is required to prevent them This treatment consists of

1 Rest in bed or, at least, complete prohibition of walking or standing for a month or two or even a great deal longer to permit development of collateral circulation and until the pain has completely disappeared It should be followed by extremely gradual return to partial activity

The position in which the affected limb should be kept when at rest is that which secures as nearly normal a color as possible This in most of these cases is when the limb is somewhat depressed When the degree of downward obliquity necessary to produce the optimal circulatory condition has been discovered, this should constitute for the patient his own "horizontal," which should be maintained by arrangement of the bed during periods of rest as well as during sleep Whenever it appears that the veins stand out too prominently in a leg at this slightly oblique decline, it should be lifted up for a moment to favor return circulation

PRESCRIPTION 1—Concentrated Ringer's Solution

R	Sodium chloride	270.00 Gm
	Dried calcium chloride	20.00 Gm
	Potassium chloride	10.00 Gm
	Water to make	1000.00 cc

Dilute twenty five times e. g. add 80 cc (approximately 5 table-spoonfuls) to 2000 cc (half a gallon) of water for daily consumption

2 Hydremic plethora (a) Ringer's solution The regular and continued daily drinking of from one-half to 1 gallon of Ringer's solution (prescription 1) is probably a rational attempt at improving the circulation in the threatened tissue, a result that could not be secured by mere water drinking, as salt solutions leave the system less readily than that much water Appearance of even a trace of edema would, of course, set the limit to this treatment

(b) Hypertonic saline phlebotomy In cases presenting a high hemoglobin and red cell count, one might prefer the slow intravenous injection of from 2 to 5 per cent sodium chloride solution, employing 150 cc for the first injection and 300 cc for all subsequent injections, given three times a week These injections produce a certain amount of blood destruction, which might possibly be beneficial, and they should be stopped if anemia is produced Results may not be evident until the treatment has been maintained for several months

3 Hyperemia treatment When thermic measures are applied in these cases, it must be remembered that high or low temperatures are borne with impunity only by tissues well supplied with blood Hence the more the circulation of the limb is interfered with, the nearer the neutral point must be the temperature of the application, especially is this true during periods of phlebitis, acute or recent thrombus formation, or when phlegmons are present While the treatment should be relatively mild, this should be given for fifteen to

forty-five minutes four to six times daily alternating with the postural treatment, so as to maintain the best possible circulatory activity over the greater part of the day and evening

(a) A lamb's wool and flannel bandage covering of the entire affected limb is the mildest degree of this form of therapy and should be employed in all cases unless more active measures are used, and in intervals between these the limb should be guarded by special care against pressure sores at heel, calf or toes

(b) An electric light cradle is a more powerful measure when applied as nearly constantly as possible at the temperature most comfortable to the patient. This may range from 95 to 110 F. A thermostatically controlled cradle is highly desirable, for excessive heat increases the pain. In the absence of a thermostat the patient may be instructed to turn on or off as many lights as are required for the greatest comfort. The part affected by trophic disturbances or gangrene should be carefully protected against any considerable degree of heat

(c) Warm compresses are indicated if the skin is dry, extreme heat being scrupulously avoided

(d) Pyretotherapy (q v) may be used. The therapeutic induction of fever is a valuable form of treatment and is employed particularly in thrombo-angitis obliterans. The most common method is the intravenous injection of foreign protein (typhoid vaccine in gradually increasing doses). During the period of chill there is a generalized vasoconstriction, which can be controlled by the administration of alcohol. Thrombosis has been reported occasionally, probably a result of initial vasoconstriction. Physical measures for the induction of fever are effective and with them the initial vasoconstriction does not occur. The optimal temperature elevation for vasodilatation ranges between 100 and 103 F. Pyretotherapy is a rather severe procedure unsuitable as a general measure in elderly persons or those worn by long continued pain, sleepless nights, infection and toxic absorption from extensive gangrene. It is contraindicated in arteriosclerosis obliterans as well as in diabetes, particularly since fever lessens dextrose utilization

(e) Medicinal vasodilators, such as nitrites, are too transient in their effects to be of any value. Theobromine Sodio-Acetate in 0.5 Gm capsules, of which two may be given three times daily after meals, is of value in angiospastic cases, both thrombo-angitis obliterans and arteriosclerosis, but is useless in Raynaud's disease. Iodide might be given in arteriosclerotic cases (q v) for whatever value it may possibly have in this condition

(f) Periarterial sympathectomy of the large (femoral) artery may possibly be of value in cases in which there is a markedly vasospastic element, as in Raynaud's disease. The more diseased the blood vessels, the less is to be expected from this operation

4 Enhancing development of collateral circulation. Most of these methods are contraindicated in the presence of recent extensive thrombosis or gangrene, by the presence of phlegmons, or if they produce or increase pain

(a) Buerger's postural treatment is intended to induce hyperemia. It consists of three periods: (1) elevation for the minimal time to secure blanching of the

foot (from thirty seconds to three minutes), (2) the foot hanging down for one or two minutes beyond the time required for maximal redness, unless pain is produced, when the time must be shortened, (3) the horizontal rest position for three minutes or longer, as required by the patient, so that six or seven repetitions of these cycles, which constitute a "seance," should not be too fatiguing. These seances, which last about an hour, should be alternated with some form of heat treatment for a half to three quarters of an hour and continued well into the evening, one hour's rest being allowed after breakfast and supper and two hours for an afternoon nap

(b) Contrast baths may be applied up to the knee or the elbow, possibly twice a day, starting with immersion in hot water (not above 110 F) for five minutes, following this by a dash of or very brief immersion in cold water (not below 50 F), in alternation several times. The seance is finished by brisk drying after a hot immersion, to insure a good circulatory reaction

(c) Intermittent compression of the main artery of the limb for one minute and releasing for five minutes, to secure reactionary redness, may be employed. These alternations are maintained for an hour and may be carried out manually or by means of the blood pressure cuff with a special cushion over the femoral or brachial artery. This may not be a practical procedure, as it often results in increased pain

(d) Short alternations of positive and negative pressure by means of automatic apparatus advocated and devised by Landis and Gibbon and by Hermann and Reid (passive vascular exercise) is theoretically correct. It was designed as a method of treatment for those

PRESCRIPTION 2—Compound Analgesic Capsules

B Extract of hyoscyamus	0.10 Gm
Phenobarbital	0.50 Gm
Acetanilid	1.00 Gm
Acetylsalicylic acid	3.00 Gm

Mix and divide into ten capsules

Label: One every four hours as required for pain

more severe forms of vascular disease in which the simpler measures were not successful. It is to be hoped that expectations will be realized, but its actual value will be established only by further observations

5 Analgesia. Pain not sufficiently relieved by the measures described indicates the use of analgesics. Acetylsalicylic acid (a 0.3 Gm tablet or capsule every two to four hours) is perhaps the least objectionable, unless it produces sweating. If it does, it might be combined with Extract of Hyoscyamus (0.01 Gm per capsule). If it does not suffice to relieve the pain, Acetanilid (0.10 Gm) might be added to it, and, especially at bed time, Phenobarbital (from 0.05 to 0.10 Gm). When all four ingredients are indicated, they may be prescribed in one capsule (prescription 2). Opiates should be avoided if at all possible, but the patient should not be condemned to sleepless nights when a hypodermic injection of Morphine Sulphate (0.015 Gm) can secure sleep. He should not be entrusted with its self administration, however, for fear of engendering the habit. The lavish employment of Codeine Phosphate (0.06 Gm) is hardly justifiable in charity hospitals, because it is inferior to morphine as an analgesic and much more expensive, and here the patient's medicine is under complete control. In private practice it might be preferred because it is less habit producing

The burning pain of trophic ulcers might be relieved by an ointment containing 5 per cent of Procaine and 10 per cent of Ethyl Aminobenzoate (prescription 3). It should be remembered, however, that analgesics discourage repair. Hence their use should be discontinued as soon as possible.

PRESCRIPTION 3—Analgesic Ointment

R Procaine hydrochloride	0.15 Gm
Water	enough for solution
Ethyl aminobenzoate	0.30 Gm
Hydrous wool fat	10.00 Gm

Label: Apply directly to raw surface and cover with gauze.

Trophic Disorders and Gangrene—Conservatism pays. Early surgical amputation often results in later amputation higher up. Every effort, along the lines previously described, should be made to improve the blood supply of the limb to prevent extension of the process, and to permit time for the development of collateral circulation. The following additional local therapy is required:

(a) Small cutaneous lesions such as fissures or abrasions, require strict surgical cleanliness and are best treated dry by means of dusting with Thymol Iodide. To favor the healing of a fissure surrounded by callosities it should be converted into a shallow wound by causing exfoliation of the thickened epidermis by means of Compound Salicylic Collodion applied twice daily—not including the fissure—and soaking the feet in hot water.

(b) Infection, no matter how slight, as evidenced by redness, pain, swelling or exudation, calls for moist treatment. Warm (95 to 98 F) baths of approximately physiologic solution of sodium chloride should be prescribed for half an hour every other hour, with moist, even wet compresses of the salt solution in the intervals. If there is an infection about or under a toe nail, the latter must be at once cut in such a way as to give free escape to the exudate.

(c) Ulcer, including "perforating ulcer" is best treated by the more or less constant bath of slightly hypertonic (2 per cent) salt solution at 95 to 105 F until infection is controlled. Then baths of an hour's duration suffice, followed by the postural treatment and preceded by the dry thermal measures. For patients who cannot tolerate warm baths or the hanging down posture, an irrigation apparatus that bathes the ulcer in the patient's own "horizontal" posture may secure the desired result.

(d) For gangrene without infection, dry treatment, as by air exposure and boric acid powder under a wire cage dressing, is indicated in addition to the previously prescribed postural and heat therapy. This should be continued in dry gangrene of one or more toes, with a tendency to demarcation, until spontaneous amputation occurs.

Amputation above the knee is often, but not always, demanded when the gangrene is progressive, implicates several toes, including the big toe, creeps up the dorsum of the foot, and ascends beyond the metatarsophalangeal joints.

(e) For gangrene with infection continuous baths are indicated by the appearance of tenderness proximal to the gangrenous digit, with redness or cyanosis of the overlying skin, and even a small amount of pus exuding from this area, for the presence of these phenomena converts the dry gangrene for purposes of

therapy into the moist type. Foci of infection must be promptly opened by as many incisions as required, which can often be done without the necessity of anesthesia, as the part may be quite devoid of sensation. While the accumulation of pus must be prevented at all costs, the postural and heat treatments must now be discontinued because they may favor the extension of the infection.

If, in spite of these measures, the phlegmon extends and symptoms of sepsis appear, amputation above the knee, in the lower or middle third of the thigh, should be performed, and this as early as possible, as soon as it becomes evident that nothing is to be expected from temporizing measures. Delay merely adds to the danger. The operation may be performed under nitrous oxide anesthesia by the circular method, the femur being cut high enough to secure liberal covering of the stump in spite of retraction and a certain amount of sloughing, which must be expected in these cases. Excepting for a few catgut sutures to bring the muscles together, the wound is left fairly open, sterile adhesive plaster strips being used to approximate loosely the edges of the flaps.

Special Article

GLANDULAR PHYSIOLOGY AND THERAPY

THE GROWTH HORMONE OF THE ANTERIOR PITUITARY

HERBERT McLEAN EVANS, MD
BERKELEY, CALIF.

The earliest description of a hypophyseal disorder, that of acromegaly by Pierre Marie, and its identification with pituitary overactivity by Minkowski, was followed by reference of the reverse condition—dwarfism—to underactivity of the hypophysis by Paltanif. These deductions based essentially on a hypertrophied or diminished pituitary gland were, of course, far from demonstrating the existence in the gland of a specific ferment-like substance needed in some fundamental way before the process of growth could take place in any of the higher animals. The study of the effects of the gland substance itself could alone bring such a demonstration.

EXPERIMENTAL PRODUCTION OF DWARFISM

An immense step forward was taken by the experimental production of dwarfism when the gland was removed from young animals.¹ The classic experiments of Aschner, which were done with puppies with littermate controls, showed that an immediate arrest of growth and development was occasioned by the operation. Ablations in the rat first done by Smith followed by Richter and Wislocki,² Pencharz and

Long,³ Koyama,⁴ Thompson,⁵ Collip, Selye and Thomson,⁶ and a host of others demonstrated an immediate cessation of the daily gains in weight which characterize young animals, in fact, if the hypophysectomy is done on animals approximately 4 weeks of age and weighing from 70 to 100 Gm, the rat is incapable of increasing its body substance thenceforth, not a gram of gain in weight being possible under the best nutritive regimen and hygienic care.⁷ Dandy and Reichert have shown incapacity on the part of completely hypophysectomized puppies to increase the shaft length of any long bone, a fact readily ascertained by measurements of the diaphyses in roentgenograms. Should even slight and slow lengthening be seen proof is thereby given of partial rather than complete ablation of the anterior lobe.

EXPERIMENTALLY INDUCED GROWTH AND THE PRODUCTION OF GIGANTISM

It was conceivable of course, that the dwarfism following hypophysectomy was a secondary effect, i. e., that it was due to some obscure metabolic upset consequent on loss of the gland rather than the direct outcome of the elimination of a specifically needed substance that could be justifiably called the growth hormone. It was perhaps fortunate then, that experimental evidence of the existence of the growth hormone had been secured in another way—by the production of gigantism in normal animals, a phenomenon that would have been difficult to produce with equal ease in forms other than the rat. In 1921 Evans and Long⁸ reported the experimental production of gigantism by long continued daily conveyance to rats of extracts of the anterior pituitaries of bees. They began with daily intraperitoneal injections into a large group of animals 3 weeks of age and just weaned. An equally large group of uninjected animals that were littermate brothers and sisters of the treated ones were observed as controls throughout the experiment. In spite of the manifold disadvantages necessarily attending the treatment (introduction of foreign protein, bacteria and the like), it was evident in a few weeks that the treated animals exceeded their controls in body weight. The disparity between the treated and the untreated animals became more marked in the later epochs of life. This was due, as the growth curves showed, to the steady continuance of growth on the part of the treated animals, whereas the untreated ones showed their customary slowing or "plateau" of growth characteristic of adulthood. In growth hormone tests, advantage is

taken of the fact that the difference in treated and untreated females is greatest when growth hormone is suddenly administered to them at any time after the plateau period has been reached.

Delay in recognition of the hormone was partly due to failure to conceive that it might be incapable of action save through parenteral routes. Thus many of the early experimenters fed the substance, but, early in their work, Evans and Long had accomplished adequate test of the futility of oral dosage by massive treatment in this way. In several instances they contrived to give the sole food supply in the form of fresh anterior lobe substance, which is an excellent nutriment and is relished by the rat but not the slightest traces of growth acceleration could be discovered, there had, nevertheless, been introduced daily into the body prodigiously more of the hormone than that required to act by needle administration. In work on the growth hormone other experimenters have selected unreactive animal forms or, if they used responsive animals and administered the extracts parenterally, they gave the preparation but once or twice a week, only to be met with failure.

The gigantism or accelerated growth that may thus be induced by anterior pituitary extracts in the rat is an extreme one. It is as if one could produce human beings of 10 or 12 feet (305 or 366 cm), whereas the Basel pathologist Rösle⁹ has shown that authentic instances of human giants of 9 feet (274 cm) have never been established. Female rats will attain a weight of over 700 Gm, their littermate sisters being under 300 Gm, and males will weigh more than 900 Gm with their controls barely reaching 450 Gm. Roentgenograms or preparations of the osseous system of the giants show that dimensions of approximately one and one-half times the normal may be attained. The giants are not fat but are symmetrically proportioned, larger animals, nor does their chemical¹⁰ makeup deviate markedly from normal.

When the maximum response is reached by dosage at any one level of a particular preparation, multiplying the dose by two or by ten times shows not the slightest effect in increased growth. The limit of the body's capacity to grow has been reached and hence the limit of its capacity to utilize the hormone. At no time has a rate of growth in excess of the most rapid rate known for normal postnatal life been evoked by the growth hormone, nor does a rapid rate continue indefinitely under medication. In from fourteen to eighteen months slowing is evident and one can become convinced that forces other than epiphyseal closure operate in some unknown way to limit growth.

An abrupt fall in weight occurs after cessation of the treatment of animals with the hormone. This fortunately does not affect their skeletons. We have made elaborate measurements of the roentgenograms of such animals showing that they lose not a whit of any skeletal dimension once attained. It would therefore appear that one need never fear that the cessation of growth therapy could be followed by loss of skeletal dimensions.

7 Collip Selye and Thomson (Gonad Stimulating Hormones in Hypophysectomized Animals. *Nature* 131: 56 [Jan. 14] 1933) have pointed out an apparent capacity for temporary and limited growth on the part of very young animals after hypophysectomy. They report that if the operation is performed in rats 21 days in age and weighing less than 35 Gm, a gain of some 20 to 30 Gm may occur in the period absence of anterior lobe tissue. Since the classic experiments of Camus and Roussy (confirmed by Bailey and Bremer, Smith and others) it has been known that injury to the hypothalamus produces adiposity and it hardly seems necessary to say that if such an injury is inadvertently caused in the course of a hypophysectomy gains in post operative weight due to the adiposity will ensue.

The Function of the Anterior Hypophysis. *Harvey Lectures* 19: 212, 1924.

unusual growth produced by the growth hormone is not referable to so simple an explanation. It remained for Lee and Schaffer,³⁰ by the ingenious use of the paired feeding method of Mitchell, to show that normal rats under the influence of growth hormone will increase their body substance more than controls given the same food.

The exact mechanism of action of the growth hormone on metabolism remains entirely unknown, but a significant beginning has been made in the analysis of its effects. Since increased tissue building takes place when it is administered, it was perhaps natural to seek evidence of the retention of nitrogen, a fact first demonstrated in the studies of Gaebler³⁰ and confirmed by Lee and Schaffer. The latter observers express their results by stating that one may speak of the nitrogenous and fat-ash-free tissues as the constituents specifically influenced by the hormone. Gaebler showed that a single injection of a commercial preparation of the growth hormone (antuitrin G) in normal dogs caused an immediate and marked fall in urinary nitrogen (due to decreased urea excretion) which persisted for several days. The decreased nitrogen output would appear to be due without doubt to nitrogen storage in the tissues, for it cannot be attributed to the failure in the absorption of nitrogen (the feces are unchanged in their nitrogen content) or to renal damage (the blood non-protein nitrogen actually falls, as was first shown by Teel and Watkins³¹). Teel and Cushing³¹ pointed out that another immediate effect of these growth hormone preparations is the marked increase in water intake and output, the diuresis always follows polydipsia which is primary. Gaebler also observed a great increase in heat production with increased respiratory rate and ventilation rate. Rises of as much as 1.4 degrees in rectal temperature without infection or anæsthesia were observed. The increased heat production was due to increased oxidation of fat, evidenced in a lowering of the respiratory quotient. The large calorogenic response occurs as rapidly as after intravenously administered thyroxine but is not attributable to contamination of the growth extracts with the thyrotropic factor, for this response is also found after thyroparathyroidectomy.

The period of nitrogen storage is often clearly followed by a period of nitrogen loss, so that Gaebler feels that the preliminary effect of the hormone is to increase the "reserve" or "deposit" protein rather than to build this immediately into permanent structures. The striking effect of the hormone on protein catabolism is greatest when this is already high, as it is in adult dogs on a high protein diet with a barely positive or negative nitrogen balance.

The study of Lee and Schaffer showed that treated animals do not possess the characteristic age changes that normal rats exhibit (decreases in the proportion of water, nitrogen, fat-free dry tissue and ash, and increases in the percentage of fat) but retained with considerable exactitude their initial composition in certain chemical constituents. This propulsion of growth in the rat's adult life is therefore associated with the retention of certain juvenile chemical charac-

teristics in the tissue produced, and the question naturally arises as to whether the "youthfulness" of this tissue indicates "youthfulness" of the animal with regard to expectance of a correspondingly longer life span. Should this be the case, there would be at hand a tool for the alteration of what has heretofore been regarded as the most fundamental characteristic of living substance, i. e. its time relationship. It is unfortunate that this has not as yet been tested by studies with statistically valid numbers of animals under the constant influence of the growth hormone as contrasted with untreated controls.³² As a matter of fact, in spite of the results of the foregoing acute experiments of Lee and Schaffer, workers who have conveyed the growth hormone chronically to animals have noted rather the reverse effect, i. e., a premature senility.

Other studies, such as those of the physiologic performance (for example, fatigability) of such animals have not yet been made.³³ Possible changes in the mental acuity of animals forced to continue maximal growth have not as yet been investigated.

EXTRACTION AND CONCENTRATION OF THE GROWTH HORMONE

The growth hormone is probably itself a protein or so closely associated with proteins to make its separation from proteins extremely difficult. The purest forms of it heretofore available when analyzed continue to contain about 16 per cent of nitrogen and to give most of the classic qualitative tests for protein. The physical characteristics of these solutions (e. g., incapacity to pass certain membranes) indicate molecular dimensions of the proteins. Furthermore like some proteins, the hormone is inactivated by certain organic solvents. The hormone is a labile substance in every way, being readily destroyed by strong chemical treatment or high temperature, indeed even by moderate temperatures for any appreciable period of time. For all these reasons, attempted concentration or purification procedures have been attended with many difficulties.

For extracting the hormone from anterior lobe tissue, all workers continue to employ dilute aqueous alkali, the method originally introduced by Evans and Simpson (dilute sodium hydroxide baryta water, dilute ammonium hydroxide, and the like). These extracts are contaminated with the other physiologically active as well as inert materials that are present in this portion of the gland. The hormone, thus readily soluble in dilute alkali water along with many contaminants, is insoluble in the typical organic fat solvents (ether, petroleum ether, benzene, chloroform) but can be shown to be soluble in some of the lower fatty acids (formic and glacial acetic acids).

The problem of preliminary purification resolves itself into separation of the hormone from the greater part of the contaminating protein with which it is associated. Complete protein precipitants throw down the hormone completely, but it is impossible as yet to know whether under these circumstances one is justified in speaking of precipitation of the hormone or only of adsorption of the hormone on the precipitated protein.

31 Teel H. M. and Cushing Harvey. Studies in the Physiological Properties of the Growth Promoting Extracts of the Anterior Hypophysis. *Endocrinology* 14: 157 (May-June) 1930.

32 In spite of care the high incidence of infection and death has interfered with such past effort as has been made to test the increased youthfulness of such animals.

33 The statement of Lee and Schaffer of the increased propensity of such animals to undertake muscular effort would appear to be erroneous and attributable to the condition of hunger created by their paired feeding method of work. J. Yoshioka has shown that when food is supplied ad libitum animals under the influence of the growth hormone are actually less disposed to undertake voluntary movement.

The sole advantage of employing these complete protein precipitants would reside, perhaps, in the fact that by the dehydration of such a precipitate the hormone can be obtained as a relatively stable powder. Although this is naturally somewhat more concentrated than desiccated whole anterior lobe substance, a significant gain in purification could not be made in this way. On the other hand, by partial precipitation of the proteins the hormone may be made either to accompany the protein moiety which is precipitated or to remain to a sufficient extent in the supernatant fluid to be recovered from the latter. Precipitation of the hormone with the globulin fraction occurs when it is "salted out" with this fraction by the use of ammonium sulphate or more particularly sodium sulphate. This method has been employed by Tecl³⁴ VanDyke and Wallen-Lawrence³⁵ and Bugbee, Simond and Grimes³⁶. It separates the hormone not only from much albuminous matter but also from other contaminants, such as the blood pigment, but the "salted out" hormone (e. g. the "phylene" of VanDyke and Wallen-Lawrence) continues to be contaminated not only with much inert protein but also with recognizable amounts of gonadotropic and thyrotropic hormones and traces of the lactogenic substance.

On the other hand the majority of the proteins can be precipitated iso-electrically and although growth hormone is carried down with the precipitate, much of it remains in the supernatant and, with re-solution and repeated iso-electric precipitation the hormone is no longer present in the third or fourth isoprecipitate.³⁷ The growth hormone may thus be made to leak continuously into such supernatants, from which it should be possible to recover it quantitatively. It can be recovered in a wide variety of ways, best, Collip believes, by selective adsorption with tricalcium phosphate in ammoniacal solution. In this way a preparation called by him the "Q-extract" can be made free from gonadotropic thyrotropic and lactogenic hormones, although traces of the pituitary substance affecting the adrenal cortex are admitted to be present. This preparation is said to be sufficiently concentrated in growth hormone for maximal growth effects to be obtained in test animals by the daily administration of as little as 1 mg. of dry substance. These and preparations made by other investigators that are almost equally concentrated, are undoubtedly as yet extremely impure products, and only further extended and laborious study will lead to the crystallization of the substance properly designated the anterior pituitary growth hormone.

This substance, which may be of practical importance through its crystallization and use in cases of pronounced human undergrowth in childhood, is already of sufficient theoretical importance. Without it no higher animal is capable of increasing its body substance, without it one of the basic phenomena shown by all living things—growth—cannot take place. The detection of the exact chemical nature of the hormone may not be immediately enlightening as to the nature of growth of which so little is known. witness the recent

brilliant elucidations of the chemical structure of the vitamins, which have not thereby explained their physiologic roles. But in the former case, as in the latter, no one will gainsay that significant progress has been won in the power of mankind to exercise over the living organism an ever increasing control.

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING ARTICLE. HOWARD A. CARTER, Secretary

SHORT WAVE DIATHERMY

PRELIMINARY REPORT

FRANK HAMMOND KRUSEN, M.D.
PHILADELPHIA

Within the past year there has been an enormous sale to the medical profession of a new type of high frequency apparatus. This device has been advertised as a distinct improvement over the old type "long wave" diathermy machine. Used at first for producing general fevers, the appliance is now being sold for the production of local heating effects on the human body.

The method of treatment is known variously as short wave therapy, ultra-short wave therapy, radiotherapy, radiathermy, short wave diathermy, and so on.

The apparatus is roughly somewhat similar to the old type diathermy machine, with the exception that the electric current frequency in cycles is very much higher up to 300 times the frequency employed for diathermy.

The appliance resembles in construction the short radio wave transmitter used in police and amateur radio broadcasting, with the exception that the electrical energy instead of being dispersed from antennas, is confined between condenser plates.

Whereas the current frequency of the ordinary diathermy machine is about one million cycles per second, the current frequencies of these machines vary from ten million cycles per second (30 meter wavelength) to one hundred million cycles per second (3 meter wavelength). If the device produces radio waves of wavelengths between 12 and 30 meters, it is spoken of as a short wave machine, and if it generates wavelengths of from 3 to 12 meters, it is called an ultra-short wave apparatus.

With the ordinary diathermy machine, it is necessary to place metallic electrodes in contact with the skin or mucous membranes. With the short wave machine it is not necessary to make skin contact, insulated metallic condenser plates being placed a half inch or more from the body surface. With ordinary diathermy, heating effects are produced by conduction, whereas, with short wave diathermy, heating is due to dielectric losses in a condenser field.

The medical profession has been extensively circularized with hyperenthusiastic literature extolling the advantages of this new form of therapy. Extravagant therapeutic claims have been put forward, based largely on the writings of Edwin Schleich, a German physician whose assertions have been not only unconfirmed in this country but also partially refuted on the continent. For example, with a co-worker, Haase, he reported a selective lethal action on various microorganisms *in vitro* with specific wavelengths of short

radio waves,¹ whereas Hasche and Leunig² exposed cultures of staphylococci and streptococci in distilled water, saline solution, bouillon, milk, and on agar-plates to ultra-short waves of different frequencies and intensities for periods of time up to eight and a half hours, and they observed no inhibitory or destructive effect on the bacteria. They concluded that ultra-short waves exhibit no selective temperature or electromagnetic effects on bacteria *in vitro*.

In addition, Schliephake has made such extraordinary claims as the following: "I have treated many hundreds of furuncles, even large carbuncles, on every possible part of the body, as well as hidradenitis, paronychia, tenosynovitis, etc., and I am able to state that ultra-short wave therapy has not failed in a single case. The average time of cure was four and one half days and no patient required an incision or other operation."³ Again he writes: "So far I have treated more than twenty-five patients with pulmonary abscesses, suppurating pneumonia, large pleural empyemas. They were all cured without operation, only in the case of one patient was a large puncture made."³ Even the most credulous physician, who is willing to grant that there is much therapeutic value in short wave therapy, can hardly credit such sweeping conclusions until they are more fully confirmed by other workers. Yet the foregoing statements, and many similar ones are freely quoted in the advertising literature now broadcast to physicians.

To the average physician who has had little time to study it, the short wave diathermy machine presents certain characteristics that are distinctly appealing:

1 He is told that the device is extremely simple to operate. For example, one manufacturer writes that it is "possible for a novice to be properly instructed in a few minutes."

2 He is told that it is no longer necessary for him to fasten metal plates carefully and smoothly to the skin, as with the old diathermy machines, that "the application simply comprises embracing the area to be treated between two pad electrodes in any convenient manner."

3 He is shown pictures that illustrate two rubber pads lying loosely outside the patient's clothing as the treatment is given, and he is told that "the placement of electrodes over the clothing without the necessity of bandages, sandbags, etc., saves considerable time in application and does not require disrobing the patient."

4 He is even advised blandly by one manufacturer that, "since no electrical contact is made, 'arcing' and burns are impossible."

5 He is informed that the time of treatment need be only about one-third that of a diathermy treatment.

6 He is led to believe that there is a uniform deep heating of the tissues between the two electrodes.

As a matter of fact

1 The apparatus is not entirely safe or simple to operate, and it is, I believe, the consensus among experts in physical therapy that these machines need further perfection and more clinical study. The reputable manufacturers view with alarm the fact that they are forced to rush hastily to the making of these machines in order to protect themselves in a highly com-

petitive field. One engineer, representing a high frequency concern, speaking to a group of physicians, recently made the statement: "We, as manufacturers, have a great deal to learn as regards the construction of short wave equipment."

Two concrete examples of imperfections in manufacture have been noted in hospital clinics. In one instance a short wave machine was being used for treatment, when the rubber insulation on one of the treatment electrodes suddenly burst into flame and slightly burned the patient before the technician could remove it. In another case an ultra-short wave machine was being used to treat a patient when the electrode cables came in contact with each other, after several minutes the cables suddenly flamed at the point of contact (as shown in the illustration), scorching the front of the apparatus and burning the technician's hands when she pulled the cables loose but, fortunately, doing no other damage. It would seem that, even with fairly heavy insulation of cables, a concentration of heat may occur

Apparently well insulated new electrode cables of ultra-short wave machine after they had burst into flame when they simply came in contact with each other during a treatment.

when they touch each other sufficient to cause the rubber covering to burst into flame. One physician reports having a rubber cable burn during a short wave treatment when it came into contact with the edge of a metallic bed.

There is still no agreement as to which wavelength is most satisfactory for therapeutic purposes. At present there is no accurate method of measuring dosage with these devices. Kovacs⁴ has stated that "it is evident that short wave local therapy in its present stage offers only a crude mode of regulation and control of dosage."

2 The application of electrodes is not a simple matter. It is stated by the experts in this field that it is necessary to space them extremely accurately at measured distances from the skin surface in order to obtain proper localization of heat. No satisfactory official electrodes have yet been devised. There is

1 Haase, W. and Schliephake, E. Versuche über den Einfluss kurzer elektrischer Wellen auf das Wachstum von Bakterien. Strahlentherapie 40:133 (March) 1931.

2 Hasche, E. and Leunig, H. Dosage of Ultrashort Waves. Influence of Intensity and Frequency on Bacteria in Vitro. Strahlentherapie 50:351 (June) 1934.

3 Schliephake, E. Kurzwellentherapie. Jena: Gustav Fischer, 1932.

4 Kovacs, Richard. Electrotherapy and the Elements of Light Therapy. ed. 2. Philadelphia: Lea & Febiger, 1935.

great difficulty in avoiding concentration of heat from the cables leading to the electrodes, because the field that is produced by the cables is nearly as powerful as the fields of the electrodes themselves

3 It is most dangerous to attempt to give these treatments through clothing. One reputable manufacturer advises "If you use the electrodes over clothing you are bound to produce perspiration, and will and must get burns." Kovacs⁵ writes "The application of electrodes over the clothed body makes a close observation of incipient burns of the skin impossible, it also breeds carelessness in neglecting the elementary rule of close inspection of the parts before and after every treatment."

4 In the condenser field between the electrodes, hot spots occur constantly in areas of moisture. In more than a year's observation of short and ultra-short wave machines, I have observed that, whenever the part becomes heated and perspiration forms there is annoying burning. While this burning is relatively infrequently followed by anything but the mildest of first degree burns of the skin still, the phenomenon is one of the greatest drawbacks to short wave diathermy. Even when every effort is made to keep the skin dry by means of dry towels or dry felt next to the skin, burning sensations are far more common than is the case with ordinary diathermy. In addition, deep tissue burns of severe nature have been reported by several workers. Schmidt⁶ reports a severe coagulation of the tissue beneath the skin in one case, with little change in the skin itself. Another investigator reports that, while testing a short wave machine on himself, he received a severe 1½ inch circular burn of the skin "without having felt it at the time of its production." Coulter⁷ has reported the observation of skin burns from short wave therapy "entirely comparable in their appearance to those produced by ordinary diathermy." Not only, therefore, is the statement that "burns are impossible" entirely fallacious, but also one may go further and say that, in the absence of actual burns burning sensations are more common than with ordinary diathermy, even when the most careful technic is employed.

5 The fact that it is claimed that less time is necessary to heat the tissues with short radio waves than with ordinary diathermy merely emphasizes the point that these machines may have a greater energy output and hence are potentially more dangerous.

6 There are, to date, very little clinical data to show that short wave therapy has any great advantage over ordinary diathermy. Whereas Schliephake⁸ claims superior penetration, Schultze and Rach⁷ applied short waves to the pelvis, with electrodes over the symphysis and under the buttocks, measured the temperature in the urine-filled bladder, vagina and rectum with alcohol thermometers, and concluded that a pronounced heat effect could not be recognized in these regions although a noticeable heating of the skin could be ascertained and the patients felt definite sensations of heat.

CONCLUSIONS

Before short wave and ultra-short wave diathermy machines are used extensively

1 They should be improved in construction, and the manufacturers should specify definitely the wavelengths of the apparatus and their output in watts

2 Fire hazards should be eliminated

3 An accurate method of measuring dosage should be perfected

4 More data concerning the physiologic effects of the waves they produce should be amassed

5 The idea that the apparatus is simple to operate and that treatment may be given through the clothing should be dispelled

6 The technic of application should be improved so that the danger of burning sensations is lessened

It would seem that with further study by physicists and engineers concerning the proper methods of constructing apparatus and with further clinical investigation by especially skilled physicians in hospital physical therapy clinics, short wave diathermy may prove to be a useful therapeutic agent. But at the present time many of these devices have not been sufficiently perfected, and it must be confessed that knowledge of the exact physiologic effects of these waves is very limited. Extensive employment of these machines at the present time can lead only to unsatisfactory results and may cause condemnation of a method of treatment that might otherwise be found serviceable.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

AMINOACETIC ACID

Modern treatment of the muscular dystrophies has been based primarily on the assumption of a neurogenic or myoneural origin, thus despite the observations of Duchenne,¹ Erb,² and Friedrich,³ which demonstrated definite pathologic localization within the affected muscular tissue per se. Very recently a number of independent workers in the field of muscular metabolism have published studies which lend support to these earlier views.

Brand, Harris, Sandberg and Ringer⁴ were first to recognize the relationship of aminoacetic acid (glycine, glycocholl) to the origin of creatinuria, although as early as 1921 Gibson and Martin⁵ had demonstrated a greater creatine excretion in animals on diets high in protein, particularly when 55 Gm of a total of 75 Gm of dietary protein was in the form of gelatin⁶.

Beard and Barnes⁷ found that, while the individual feeding of all amino acids increased the creatine content of striate muscle in rats, the magnitude of this increase was in no wise proportionate to the respective effect on urinary creatine. In these studies aminoacetic acid (glycine) was shown to have a more pronounced effect on creatine excretion than any other amino acid, while glycoxyamine, histidine, valine and a number of others proved much more effectual in elevating the muscular creatine. No relationship to specific dynamic action could be discerned and the authors conclude, as verified by Luck,⁸ that creatinine and creatine are not exclusively endogenous but may

depend substantially on the exogenous protein of the diet, quantitatively and qualitatively.

Brand and his co-workers,⁴ Milhorat, Techner and Thomas,⁹ Boothby¹⁰ and Kostakow and Slaack¹¹ coincide in the observation that, in the progressive and pseudohypertrophic types of muscular dystrophy, the urinary excretion of creatine is considerably augmented and that such individuals excrete ingested creatine practically quantitatively. Conversely, Boothby has shown that in myasthenia gravis the urinary creatine is so scant as to reduce the creatine nitrogen/preformed creatinine nitrogen ratio to the neighborhood of 0.1/1.0, as compared with a like ratio in the muscular dystrophies of from 1/1 to 3/1. Apparently, then, myasthenia gravis is etiologically distinct from muscular dystrophy, not only clinically (age of onset, character, course, localization and so on) but in the nature of the disturbance of intrinsic muscular metabolism as well. Contradictory though these observations may seem, aminoacetic acid has proved of definite and heretofore unequalled benefit in the treatment of diseases of either class. With reference to the different clinical entities that have been described under the general heading of primary muscular dystrophy, it is not inconceivable that with further information it may be shown that they have a common etiologic or chemical basis. The various clinical entities as now referred to may actually be different phases of the same morbid process.

Milhorat and his co-workers⁹ treated six cases of muscular dystrophy with aminoacetic acid, three each of the progressive and the pseudohypertrophic types. In these cases, while 5 Gm. of aminoacetic acid daily was sufficient to produce an increased creatinuria, dosage of from 15 to 20 Gm. resulted in an increase varying from 100 to 1,000 per cent over the original quantity of creatine excreted. Following two to three weeks of treatment the creatinuria in these patients fell to the initial control level irrespective of the continuance of aminoacetic acid, and, coincident with these metabolic changes, noteworthy clinical improvement was seen in all. (On withdrawal of aminoacetic acid the original metabolic state is said to return within three to four weeks.) Initially, a curious "crawling or rumbling" sensation appeared in the more affected muscle groups, at times sufficiently severe to prevent sleep. This feeling is reported to diminish soon (from three to four days) after the creatinuria begins to drop to the initial level and to disappear within a few days to a few weeks after that level is reached, provided aminoacetic acid is continued. A significant amelioration of the intense fatigue is then said to ensue, resulting in the desire and ability of the patients to perform movements impossible for a considerable time previously. Finally, improvement is great enough to allow of the resumption of activities long since impossible (climbing stairs, arising from the floor unaided, bicycle riding, and the like). Though all cases are most favorably affected subjectively, the time required to attain given degrees of objective improvement is reported as widely variable with the individual patient. Following cessation of aminoacetic acid therapy, improvement continues until the previously described regressive metabolic changes take place, at which time relapse becomes apparent. Resumption of aminoacetic acid, conversely, brings about an equally prompt remission. This series was controlled by three unrelated cases (one of severe chronic articular rheumatism, one of congenital idiocy and one of amyotrophic lateral sclerosis). In these controls under aminoacetic acid, no increase in creatinuria, no improved feeling of well-being, no demonstrable metabolic change, and no increase in ability to retain ingested creatine was noted. In short, the administration of aminoacetic acid to the control group was without any notable effect. The authors conclude that in view of these observations, it cannot be assumed that the action is due to any nonspecific irritative response to aminoacetic acid but rather to an at present obscure but fundamental role of that amino acid in the physiology of striate muscle. It may

be observed in this connection that there are many observers now convinced that the phosphocreatine content of muscle bears a significant and essential relationship to muscular contraction. Kostakow¹² has verified these reports in part in a series of sixteen cases, in fifteen of which the disease was found to have been inherited as a sex-linked recessive among a familial group of fifty-five individuals studied. He notes further (a) that improvement is inversely proportional to the duration and rate of progression of symptoms (but not to the age of the patient) and directly proportional to the extent to which affected muscles remain capable of action, and (b) that active patients require much more aminoacetic acid than those at rest.

Boothby¹³ records twenty-six cases of progressive muscular dystrophy with no deaths or relapses, and a general improvement in the subjective state, but only four of these exhibited any indication of regaining previously lost ability to perform some particular movement. The biochemical phenomena outlined in other studies are verified and it is concluded that with aminoacetic acid the progressive downward course of the disease is at least effectually halted. In myasthenia gravis, however, more extensive investigations are reported, involving a series of forty-seven patients under treatment for periods varying from three to eighteen months. Of these (all of whom received 30 Gm. of aminoacetic acid daily) thirteen have returned to their usual work and may be classed as complete recoveries, nine are greatly improved and able to perform moderate or part time work, seventeen are moderately improved (most of this group having been under treatment but a short time), and one has been lost in the follow up. Of the seven who died, but two showed no improvement in spite of treatment, one died the day following admission, another died of pneumonia, another was a suicide while two forsook treatment after satisfactory initial improvement to die of the disease. Thus but three of forty-three patients (about 7 per cent) receiving optimal treatment died and more than 50 per cent of the entire group are or have been working full or part time for a year or more. Occasional minor relapses are reported in all, but of no appreciable portent or magnitude. The question of the effect of aminoacetic acid on creatinuria in myasthenia gravis is contradictory, however. Boothby¹⁰ and Adams and Power¹⁴ reported an increase under treatment, while Schmitt¹⁵ claimed an equally significant or proportionately greater decrease. Schmitt in his two cases reports practically complete cures obtained in advanced stages irrespective of the conflicting laboratory studies.

Other studies involve the general "pick-me-up" qualities of aminoacetic acid when it has been employed in a multitude of complaints all centering about the normal individual with "that tired feeling."¹⁶ As expressed by Moersch,¹⁷ Hench¹⁸ and Wilder,¹⁹ the difficulties involved in obtaining critical evidence in such conditions are so involved that extensive studies are necessary before any conclusion may be reached and the Council does not feel that such use can be recommended. It may be cited, though, that Wilder and his son demonstrated on themselves a decrease (average) of better than 50 per cent in the urinary creatine excretion during vigorous exercise after taking aminoacetic acid for one week.

From the many studies reported on aminoacetic acid it is quite apparent that its use in the treatment of myasthenia gravis and muscular dystrophy of either the progressive or the pseudo hypertrophic type offers the patient greater hope than any form of treatment heretofore employed. Its use in other conditions cannot as yet be recommended on the basis of the meager investigations thus far reported. The Council declared aminoacetic acid acceptable for New and Nonofficial Remedies.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES OF WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS IEECH, Secretary

AMINOACETIC ACID—Glycocoll—Glycine— $\text{CH}_2\text{NH}_2\text{COOH}$

Actions and Uses.—Observations of a number of workers have shown aminoacetic acid (glycocoll, glycine) to exert a significant effect on urinary and muscle creatine in patients the victims of myasthenia gravis, and progressive or pseudo-hypertrophic muscular dystrophy. Coincident with the altered creatine metabolism definite, and in many instances remarkable degrees of clinical improvement or amelioration of symptoms have been reported. In practically every case irrespective of the actual degree of objective improvement noteworthy alteration of the patients' subjective state occurs with significant diminution in the ever present and harassing sensation of fatigue.

While some observations would indicate that aminoacetic acid may exert an action in all forms of fatigue, this work has not been critically controlled and for the present at least its use had best be confined to the three pathologic states enumerated.

Dosage.—Aminoacetic acid is administered in an average dosage of from 20 to 30 Gm daily usually in some palatable liquid vehicle such as milk. Some workers have employed ephedrine in $\frac{1}{10}$ to $\frac{1}{8}$ gram dosage three or four times daily conjointly with aminoacetic acid. Evidence for or against such use is controversial and the decision must depend on the individual case until more convincing studies are reported.

Aminoacetic acid occurs as a light white odorless crystalline powder possessing a sweetish taste. It is freely soluble in water very slightly soluble in alcohol and practically insoluble in ether. Aminoacetic acid turns brown at about 228° C and melts with decomposition (foaming) at 232-236° C (U S P X method).

Treat separately 2 cc. portions of an aqueous solution of aminoacetic acid (1:10) as follows: Add 0.3 cc of diluted hydrochloric acid and 0.3 cc of sodium nitrite solution (1 in 2); a vigorous evolution of gas occurs. Add 1 cc of ferric chloride solution; a deep wine color forms which disappears after addition of excess diluted hydrochloric acid solution and reappears on addition of excess stronger ammonia water. Add 0.1 cc liquefied phenol solution and 5 cc sodium hypochlorite solution (2 per cent active chlorine); a blue color forms.

Ten cc of an aqueous solution (1 in 10) conforms to the U S P X test for heavy metals. Dissolve 3 Gm of aminoacetic acid in from 30 to 40 cc of water and treat according to the U S P X turbidimetric test for chlorides; the turbidity is not more than that produced in a control test made with 0.25 cc of fiftieth normal hydrochloric acid. Dissolve 3 Gm of aminoacetic acid in water and treat according to the U S P X turbidimetric test for sulphates; the turbidity is less than that produced in a control test made with 0.2 cc of fiftieth normal sulphuric acid. Boil 10 cc of an aqueous aminoacetic acid solution (1 in 10) for one minute and set aside two hours; the solution appears as limpid and mobile as before boiling.

Heat about 0.4 Gm of aminoacetic acid accurately weighed for four hours at 100° C; the change in weight is not more than 0.0002 Gm. The ash from 0.4 Gm weighs not more than 0.0004 Gm. Treat from 0.26 to 0.32 Gm of aminoacetic acid accurately weighed according to the procedure for nitrogen determination in Medical War Manual No. 6 Laboratory Methods of United States Army 1919 p. 222; the nitrogen content is not less than 18.4 per cent nor more than 18.8 per cent.

Aminoacetic Acid-Pfanstiehl—A brand of aminoacetic acid N N R

Manufactured by the Pfanstiehl Chemical Co. Waukegan Ill. No U S patent or trademark.

ORTAL SODIUM (See THE JOURNAL, March 24, 1934, p. 928)

The following dosage form has been accepted:

Capsules Ortol Sodium 5 grains (0.3 Gm.)

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

WARRANTY SIEVED GREEN BEANS

Manufacturer.—The Nielsen Corporation, Ltd., Oakland, Calif.

Description.—Sieved green beans prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacturer.—Succulent green beans are delivered to the plant, immediately washed, and subsequently processed and canned by essentially the same procedure as described for Warranty Sieved Spinach (THE JOURNAL, Feb. 2, 1935, p. 399).

Analysis (submitted by manufacturer)—

	per cent
Moisture	93.2
Total solids	6.8
Ash	0.5
Sodium chloride	0.04
Fat (ether extract)	0.1
Protein (N \times 6.25)	1.5
Reducing sugars as invert sugar	1.4
Sucrose	0.3
Starch	0.9
Crude fiber	0.7
Carbohydrates other than crude fiber (by difference)	4.0

Calories.—0.2 per gram 6 per ounce

Vitamins.—The method of preparation and processing insures the retention in high degree of the natural vitamin values.

Claims of Manufacturer.—Specially intended for infants, children and convalescents, and for special smooth diets. Only warming is required for serving.

DELICIA OLEOMARGARINE

Manufacturer.—John F. Jelke Company, Chicago

Description.—Margarine prepared from refined coconut oil, water, cottonseed oil, cultured milk, salt, monostearyl sodium sulphate and sodium benzoate (0.1 per cent).

Manufacturer.—The method of preparation is essentially the same as that described for Jelke's Good Luck Vegetable Oleomargarine (THE JOURNAL, July 28, 1934, p. 260).

Analysis (submitted by manufacturer)—

	per cent
Moisture	17.6
Ash	3.5
Sodium chloride	3.4
Fat (ether extract)	78.5
Protein (N \times 6.25)	0.3

Calories.—7.1 per gram 202 per ounce

THAMES VALLEY ASSORTED DICED VEGETABLES

Distributor.—The Yantic Grain & Products Co., Norwich, Conn.

Packer.—The Larsen Company, Green Bay, Wis.

Description.—Mixture of carrots, potatoes, celery, green beans, cabbage, peas, corn, lima beans, onions, sweet peppers, salt and water prepared by efficient methods for retention in high degree of the natural mineral and vitamin values the same as the accepted Larsen's Veg-All—"A Magic Garden" for Soups, Salads, Vegetable Dishes (THE JOURNAL, Aug. 12, 1933, p. 525).

DANNY BOY HULLESS POP CORN

Manufacturer.—The Albert Dickinson Company, Chicago, and Minneapolis.

Description.—Canned popcorn kernels with a proper moisture content for popping. The same as Dickinson's Little Buster Hulless Pop Corn (THE JOURNAL, Sept. 17, 1932, p. 997).

SATURDAY, APRIL 6, 1935

OBITUARIES OF PHYSICIANS PUBLISHED IN 1934

During 1934 the number of obituaries of physicians published in THE JOURNAL totaled 3,393, including 162 Canadians. The obituaries of 3,231 physicians of the United States were published, as compared with 3,209 in 1933. The total number includes also 4 each in Puerto Rico and China, 3 in the Philippine Islands, 2 in India and 1 each in Panama, Hawaii, Japan, France, England, Siam, Persia and Cyprus. The obituaries of 73 women physicians were published, as compared with 83 in 1933. Graduates of medical schools in the United States for the fiscal year ended June 30, 1934, numbered 5,038. Deducting the number of physicians whose obituaries were published, there was a net addition to the ranks of the profession for the year of 1,807.

Ages—The average age at death of those classified as of the United States was 64.3, as compared with 64.4 in 1933. One physician lived to be 100 years old and 46 others lived to be 90 or more. There were 5 who died under 25 years of age. Twenty-four physicians died between the ages of 25 and 29, 50 between 30 and 34, 68 between 35 and 39, 88 between 40 and 44, 158 between 45 and 49, 297 between 50 and 54, 388 between 55 and 59, 486 between 60 and 64, 495 between 65 and 69, 426 between 70 and 74, 354 between 75 and 79, 249 between 80 and 84, and 142 who were more than 85. More deaths occurred in March than in any other one month.

Causes—Heart disease was again the leading cause of death. Some contributory causes are included in the tabulation, as they have been in former years. A report that the cause of death was "chronic nephritis and heart disease," for example, is so published in THE JOURNAL and is recorded on the statistical charts under both diseases. Of the causes of death from heart disease, endocarditis or myocarditis was specified in 326, coronary thrombosis in 137, angina pectoris in 119 and pericarditis in 1. Cerebral hemorrhage was the second most frequent cause reported, with 336

deaths, 16 additional deaths were reported as due to paralysis. Pneumonia was the third most frequent cause, lobar pneumonia having been reported in 248 cases and bronchopneumonia in 72. Fourth on the list was cancer. Of 296 deaths reported as due to cancer, the stomach and liver were affected in 64 cases, the prostate gland in 35, the intestine in 28, the buccal cavity in 4, the female genital organs in 1 and the skin in 1, in 163 cases the part affected was not specified. Arteriosclerosis caused 280 deaths and other diseases of the arteries 2, nephritis 195, of which 33 cases were specified as acute nephritis, uremia 107, embolism and thrombosis, exclusive of coronary thrombosis, 78, diabetes mellitus 66, hypertension 56, tuberculosis of the respiratory system 50, and other forms of tuberculosis 6, diseases of the prostate 40 and other diseases of the genito-urinary system 46, cirrhosis of the liver 32, septicemia 30, influenza and ulcer of the stomach each 25, appendicitis 20, peritonitis and intestinal obstruction 17, gangrene 14, leukemia 13, pernicious anemia 11, cholecystitis, erysipelas and paralysis agitans 10 each, brain tumor, heat prostration and meningitis 9 each, encephalitis and streptococcal infection 8 each, agranulocytic angina and Hodgkin's disease 7 each, asthma, biliary calculi and hernia 6, aneurysm, diverticulitis and mastoiditis 5 each, cellulitis and pleurisy 4 each, chronic bronchitis, empyema, osteomyelitis, otitis media and toxemia 3 each, carbuncle, diphtheria, dysentery, emphysema, esophageal varix, dementia paralytica, other diseases of the nervous system, goiter, Ludwig's angina, myelitis, pellagra, sprue and typhus 2 each. Among other unusual causes of death given for one case each were acute septic arthritis, acute toxic neuritis, alcoholism, Alzheimer's disease, amebic dysentery, anaphylaxis, arsenic poisoning, blackwater fever, cerebral hyperemia, cholangitis, diverticulum of the esophagus, exhaustion and exposure, food poisoning, furuncle, glaucoma, traumatic ileus, Korsakoff's syndrome, Landry's paralysis, malaria, therapeutic malaria, malnutrition, morphine poisoning, multiple myeloma, multiple sclerosis, muscular atrophy, myasthenia gravis, paratyphoid, parotitis, pemphigus, polyneuritis, Raynaud's disease, retroesophageal fistula, scarlet fever, sinusitis, thrombo-angitis obliterans and tularemia, typhoid, and x-ray burns.

Accidental Deaths—One hundred and forty-one physicians died as the result of accidents in 1934, compared with 158 in the previous year. Automobile accidents accounted for 69 deaths, 6 less than in 1933. In 1934, deaths from falls numbered 35, the second largest number due to accidental causes. Ten deaths were caused by drowning, 6 by shooting, 4 by burns, 3 by overdoses of medicine, and 2 each by gas, airplane accidents and street car accidents. Three physicians died in the *Morro Castle* disaster. One died of carbon monoxide poisoning and 1 of x-ray burns, 1 was crushed by an elevator and in 2 cases the nature of the accident was not specified.

Smicides and Homicides—Suicide was the cause of 75 deaths in 1934, 5 more than 1933. Shooting accounted for 44 of these deaths, poison for 9, hanging for 6, gas and cut artery 3 each, jumping and carbolic acid 2 each, strangulation, carbon monoxide and stabbing with a surgical instrument 1 each. In the remaining cases the method was not reported. There were 6 homicides by shooting.

Positions—Among the decedents were 174 who were or had been teachers in medical schools, 353 who served in the World War, 31 veterans of the Civil War, and 54 veterans of the Spanish-American War. One hundred and twenty-two had been health officers, 85 members of boards of education, and 50 members of boards of health. There were 48 coroners, 45 mayors of municipalities, 32 members of state legislatures, 21 members of state boards of medical examiners, 19 members of the U. S. Army Medical Corps, 7 of the U. S. Navy Medical Corps, and 9 of the U. S. Public Health Service. Twenty-eight authors, 22 druggists, 16 bank presidents, 15 members of city councils, 11 missionaries, 9 editors, 7 dentists, 7 lawyers, 5 postmasters, 2 clergymen, 2 judges, 2 justices of the peace and 1 lieutenant governor were included.

Association Officers—The obituaries published in 1934 of physicians who were or had been officers of the American Medical Association included 2 past presidents, 2 trustees and 9 section officers. Twenty-eight members or former members of the House of Delegates died during the year. Twenty-one presidents or former presidents, 1 president-elect and 5 secretaries of state societies were included among the officials.

CALIFORNIA MEDICAL SOCIETY ENDORSES SICKNESS INSURANCE

Following the session of the House of Delegates of the American Medical Association in Chicago in February, a meeting of the house of delegates of the California Medical Association was held in Los Angeles on March 2. A special committee of five, appointed by the house of delegates of the California Medical Association in 1934, submitted a report of a survey of health care in California and a plan for the administration of health insurance. This committee, with an advisory council, had made the survey, which involved a study of medical practice as conducted by physicians, dentists, osteopaths, hospitals and clinics, and a direct study of the health care of the public obtained through 48,000 questionnaires secured from families by field workers and by mail. The cost of the survey was approximately \$80,000, of which some \$25,000 was supplied by the California Medical Association and the remainder through an appropriation by the government.

The committee of five rendered a majority report signed by four members to the effect that health service be furnished on a voluntary basis. In accordance with

the instructions of the California house of delegates given in 1934, the committee prepared a health insurance bill but recommended that it be not adopted. At the same time Dr. Alson R. Kilgore presented a resolution that the California Medical Association establish an organization for the specific purpose of providing means whereby the cost of care of sickness and injury for those of moderate and low incomes may be met by the method of periodic payments in advance, that this organization provide for meeting costs of professional service and hospital care, and that the council of the society perfect a plan of organization for these purposes. Subsequent provisions requested the inclusion in such plans of the free choice of physician, dentist and hospital, and maintenance as far as possible of the traditional patient-physician relationship. It was also requested that the plan be developed so as to operate without profit to any one. After considerable debate, both these reports were referred to a reference committee.

Following this statement, Dr. Rodney A. Yoell presented a minority report recommending that the house of delegates of the California Medical Association endorse the principle of compulsory health insurance, submitting with this recommendation a bill in support of the plan with the idea that this bill be the basis of discussion of the California Medical Association with the senate interim committee of the California legislature. This also was referred to the reference committee.

The council of the California Medical Association submitted to the house of delegates six questions as to the point of view of that body in relationship to medical practice in California and also presented some resolutions, which were referred to a special reference committee. These resolutions concerned the relationship of the medical association to the county hospital, the corporate practice of medicine and compensation for medical service rendered to those on relief. After extended discussion the house of delegates approved submission to the legislature of a bill providing for both compulsory and voluntary sickness insurance, leaving it to the council and legislative committee of the association to work out the proper measures with the legislature.

In considering these actions of the house of delegates of the California Medical Association, it should be realized that there are already before the California state legislature bills legalizing the practice of medicine for profit by corporations and bills providing care in county hospitals in that state to all who apply for admittance regardless of their ability to pay, and that the federal and the state emergency relief administration in that state have been unable to work out a satisfactory plan of medical care for those on relief with organized medicine and the allied professional groups. This state of affairs may have been significant in the action finally taken. However, California seems to have been tending toward a compulsory sickness insurance

system Much depends on whether or not the medical profession after its conference with representatives of the legislature will be able to develop some system that will be satisfactory to all concerned

The proposed legislation submitted by Dr Rodney Yoell in connection with his individual minority report seems to follow closely the Epstein scheme of health insurance, with the exception that the proposed bill provides for control under a director who must be a physician and a health insurance commission of five, of which two members must be physicians

The action taken does indicate, moreover, that the majority of the house of delegates of the California Medical Association favors a system of sickness insurance including both the compulsory and voluntary forms

PROLONGED SLEEP AND PATRICIA MAGUIRE

For some time newspapers have been recording the gradual changes that have taken place in a girl, Patricia Maguire who was apparently infected some years ago with epidemic (lethargic) encephalitis and who has since that time been passing through a prolonged period of somnolence¹ In February 1932 she found herself unable to stay awake The tendency to sleep increased Gradually diplopia and other eye changes occurred Eventually the diagnosis of epidemic encephalitis was made No doubt because she had been previously connected with a local newspaper, her case has been regularly discussed in the press of Chicago and from time to time items have been widely republished by newspaper syndicates Incidentally, it is a well established fact that the publication in newspapers or the announcement over the radio of extraordinary cases, particularly when there is a romantic interest, brings to the persons concerned not only a vast correspondence from cranks but also offers of free treatment by innumerable charlatans who wish to advertise themselves, as well as quantities of foods, drugs, physical therapeutic apparatus and gifts in money It is also known that certain types of news suddenly develop extraordinary vogue At present there are being widely publicized in the press cases of "upside down stomachs," cases of absence of bones from the limbs, cases of operations on the heart, and similar extraordinary instances Moreover, the headquarters office of the American Medical Association is actually being besieged at this time with telegrams, telephone messages and letters with regard to the possible exploitation of additional cases

Long periods of somnolence are not altogether extraordinary Some time ago Drs Notkin and Jelliffe² summarized the available records of narcolepsies, representing cases not only of encephalitis but also of hypno-

lepsy, multiple sclerosis, cerebral concussions and similar pathologic disturbances The earliest case reported in scientific medical literature was that of Fourmier in 1813 Altogether there seem to have been sixty-four cases reported up to 1931 The attacks may last from a few minutes to long periods of time Thus Janet³ reported a case of sleep lasting five years and associated with a loss of the sense of reality The patient began to have periods of loss of consciousness when she was 14 years old, the first coming on during a religious ceremony At the age of 17 she began to sleep continuously and he observed her regularly until she was 23 years of age During the period when she was asleep she could be aroused briefly to hold conversations, in which it was brought out that she was possessed of the belief that she did not exist At the end of the five year period she began to sit up more frequently and finally she became able to feed herself, dress herself and walk about

Such cases are, however quite different from that of Patricia Maguire In encephalitis there are actual changes in the tissues of the brain associated with the infection, but her case is not unique, because many cases of encephalitis have been reported with long duration some in fact being prolonged to periods much beyond that already passed in the case of Patricia Maguire A careful reading of the report will indicate that as in most such cases there was but a brief period in which the patient was completely somnolent She soon began to respond to questions and more recently has been showing signs of returning intelligence

As is pointed out by Drs Notkin and Jelliffe in the article mentioned previously, it is quite possible in such cases to have a combination of both physical and functional conditions Every case should be analyzed as to the extent to which each of these elements is present Indeed, one case that they described involved a gardener, aged 46, who began to fall asleep in 1921 while talking and eating and who gradually developed epidemic encephalitis He was a patient in various institutions for a period of eleven years, on many occasions having long periods of somnolence He died eleven years after the onset of the disease from a complication of infectious conditions

No doubt there is in the study of these cases and in their discussion in the press both a morbid and a scientific interest The scientific interest is served when the incident is first reported and the facts are made known The morbid interest keeps such patients before the public year after year, together with endeavors to exploit the patient either for his own personal gain or for that of some outside interest During the recent Century of Progress exposition in Chicago, attempts were made for a public exhibition of Patricia Maguire Fortunately a sufficient sense of decency and of good taste prevailed to make this impossible

ORGANIC LIQUIDS IN HUMAN TISSUES

The identification of organic liquids in human tissues has assumed considerable medicolegal significance. A number of organic fluids of low boiling point are used in dry cleaning, as general solvents, as fire extinguishers, as anesthetics and as therapeutic agents in hookworm disease. Ethyl chloride, ethylene chloride, carbon tetrachloride, chloroform, carbon bisulphide, benzene and diethyl ether are among these substances, each is capable of producing fatal results after drinking or following inhalation of their vapors. The problem confronting the toxicologist or pathologist in cases of death due to poisoning with any of these volatile liquids is to isolate them from the organs and to establish their identity. The usual proof obtained from relying on the sense of smell is unsatisfactory and often misleading. The demand for a method for the isolation from human tissues of easily volatile organic liquids and their identification has been met by Gettler and his co-workers. By a further refinement of a technic that had previously resulted in definite proof of the presence of ethyl alcohol in normal tissues,¹ this group of New York investigators has succeeded in developing the experimental procedure² to include the isolation and identification of any low boiling organic liquid (95 C or lower). The method makes use of a specially constructed microdistillation apparatus and a newly devised microrectification flask, which are described in detail by the authors. The isolated volatile liquids are identified by means of the microdetermination of the boiling point. By this technic it is possible to isolate and identify these organic liquids readily, even though the latter may be present in concentrations as low as 0.3 cc in 500 Gm of tissue or even lower. In the case of ether, for example, it has been possible to isolate this liquid when present in concentrations of 0.06 cc in 500 Gm of tissue. The unequivocal results yielded by isolation methods should be of considerable value in medicolegal cases by assisting in the definite establishment of causes of death.

Medical Economics

ILLNESS, DEATH AND SICKNESS INSURANCE

The social function of the medical profession is to reduce the suffering from illness and postpone the time of death. The record of the fulfillment of that function is written in the steadily declining morbidity and mortality rates of modern nations and makes, perhaps, the most encouraging page in the history of the last century. Any change in the character of medical service or in the methods of giving it can rightly be tested by the effect of such change on morbidity and mortality rates. This is a test that the advocates of sickness insurance have always dodged. Their exhaustive writings give little hint of the movements in the amount of sickness or the number of deaths in relation to

population under sickness insurance systems. It is with the greatest difficulty that such facts are extracted from even the official reports of institutions and governments operating sickness insurance societies.

It is notoriously difficult to compare vital statistics of various countries. The large number of unmeasurable and not comparable elements that enter into such statistics cannot but affect any such comparisons. However, there are some facts so striking in their contrast that even though all these uncertain and imponderable elements are admitted as throwing doubt on the absolute accuracy of the results, the evidence is still too strong to be controverted.

Very few studies of the amount of sickness among industrial employees have been made in the United States. Still fewer of these present their figures in such a form as to permit anything like a fair comparison with conditions under insurance systems. Some of the methods of collecting statistics under sickness insurance tend to reduce the amount of recorded morbidity, which is always the number of days during which the patient is certified as incapable of work and therefore entitled to cash relief. There is usually a "waiting period" of from three to five days before cash payment begins. Such short time illnesses are not recorded under insurance, although they are often counted in the studies of American conditions. There is also a limit to the length of time that cash relief is granted—usually about twenty-six weeks. Any days in excess of this period are also excluded from the computations of days of sickness under insurance. Against this it is urged by the advocates of insurance that a certain amount of malingering by those who wish cash relief is inevitably included.

There are no morbidity statistics extending over a sufficient number of years in the United States to determine whether the average amount of individual illness is increasing or decreasing under the system of medical care practiced in this country. It is known that the mortality rate is steadily decreasing and that the rate of decrease has been most rapid in such diseases as typhoid, smallpox, tuberculosis, malaria and similar illnesses in which the period of disablement is apt to be very long. It is also known that each death from one of these diseases is usually accompanied by from five to ten survivals, ordinarily after an extended illness. It would seem, therefore, that the reduction in the death rate from these diseases must be accompanied by a reduction from five to ten times as great in the morbidity.

The United States Department of Commerce has published comparative mortality statistics for various nations.³ The significant thing about this study of mortality rates is that they show a continuous and fairly regular decline in all modern nations and that there is no definite correlation between the rate of decline in insurance and noninsurance countries or in the period before and after the introduction of insurance in any one country. The progress of scientific medicine and public health sanitation, higher wages and improved housing have reduced death rates in all modern countries, although nowhere can the introduction of sickness insurance be definitely shown to have influenced the rate of this reduction.

There are at least three different ways in which morbidity statistics are collected that may form the basis of comparison, although in none of these are the conditions of collection and compilation sufficiently uniform in different countries to insure any absolute accuracy of comparison. These three, which will be used in this discussion, are

- 1 Percentage of persons reporting disabling sickness annually
- 2 Average days of disability of individuals in complete coverage.
- 3 Average days of disability of individuals disabled

Most of the statistics gathered in the United States are for industrial establishments having some form of cash benefits. This at once makes difficult a comparison of private and insur-

1 Gettler, A. O., Niederl, J. B. and Benedetti-Pilcher, A. A. *J. Am. Chem. Soc.* 54: 1476, 1932. Alcohol in Normal Tissues. *Current Comment J. A. M. A.* 93: 2144 (June 11) 1932.

2 Gettler, A. O., and Siegel, Henry. Isolation from Human Tissues of Easily Volatile Organic Liquids and Their Identification, *Arch. Path.* 10: 208 (Feb.) 1935.

3 Mortality Statistics 1927, United States Department of Commerce 1930 p. 33.

ance medical practice, exaggerates the amount of illness and leads to a steady increase in the amount of recorded illness. The United States Public Health Service has compiled a table showing "frequency of specified disease groups which caused disability for eight consecutive days or longer in a group of male industrial workers employed in different industries for the years 1921 to 1928".² In 1921 the number of cases per thousand men was 9.9. By 1928 it had risen to 11.34.

The nearest comparison that can be obtained with conditions under insurance in Germany is from the statistics of over fourteen million members of the local sickness societies (*Ortskrankenkassen*).³ Here the "waiting period" is only three, instead of eight, days, which would manifestly increase the number of sicknesses. But the difference is too great to be accounted for by this, as the number of disabling sicknesses per hundred members was 584, or 584 per thousand, which is more than five times as great as in the United States under a system of private insurance that had already increased morbidity more than 20 per cent. If the utmost liberality is used in interpreting the difference in the number of disabling illnesses it is certain that the morbidity of employees, measured by the number of cases of disabling sickness per employee, appears to be at least twice as great in Germany under compulsory insurance as in the United States under private insurance.

Other statistics, offering some possibility of comparison on the basis of private practice in the United States are those collected by the Committee on the Costs of Medical Care.⁴ These included the entire population of the group studied from birth to old age. Among this group "the average disability was 164 days per illness involving any disability." Since the percentage of disabling illness is greatest in infancy and old age⁵ and the figure of 164 days includes all illness of whatever duration, while insurance statistics exclude those with less duration than the "waiting period" before cash benefits are given and those extending beyond the period of cash payment, this figure is manifestly much too high for fair comparison with insurance morbidity. The same criticism applies to comparison with the statement that "there were 71 days of disability per person in the population during the survey year."⁶ When only the adult population of working age is considered, the "number of days in bed per person" varies with age from 18 to 33 annually.⁷ This would seem to be the most suitable figure to compare with insurance morbidity.

In Germany the average days of disabling sickness to each hundred insured was 1,381.6, or 13.8 days per member. This is about five or six times as long as for adults in the United States and nearly twice the average disability period for the entire population as estimated by the Committee on the Costs of Medical Care. It may be accepted as at least the basis of a comparison of the average efficiency of private versus insurance medical practice in reducing the period of recovery from serious illness.

The comparison with the average duration of disabling illness among those suffering such illness is even more striking. In England under insurance the "average duration of claims within the year" (for incapacity to work) in 1927 was 4.2 weeks, about 29 days for men. For married women it was 5.6, nearly 40 days and for unmarried women, 7.3 weeks, or about 51 days.⁸ These figures do not include illnesses of less than four days, and all days beyond twenty-six weeks in any one case are excluded from the totals, on which the average is calculated. Some idea of the effect of the latter exclusion is obtained by

adding the number of weeks for which "disablement benefit" is paid. (This disablement benefit is a lower benefit given in case of duration of illness beyond twenty-six weeks.) In 1921 the "weeks of claim to each 100 members" under regular insurance benefit was 67 for men, and for "disablement benefit" 38 weeks, or a total of 105 weeks, or 735 days. This gives an average of 7.35 days disability per insured person, about the same as the apparent average in the United States.

However, by 1927 under insurance this rate had increased to a total of 168 weeks per hundred men, or 1176 days per insured man, annually. The rate of increase for women was far greater. The government actuary says that, comparing 1927 with 1921, the claims of men have risen by 41 per cent, of unmarried women by 60 per cent, and of married women by 102 per cent.⁹

In Germany the average duration of illness with incapacity for work among all those so incapacitated in 1885 was 141 days for both men and women. By 1925 the duration of illness had increased to 225 days for men and 28 days for women.¹⁰ Detailed figures separating the sexes are not available for later years, but by 1931 the annual average for the total for both men and women was 287 days.¹¹

In other words if one is to assume that medical service is to be measured by its success in reducing the suffering due to illness among industrial workers in the lower wage class, these figures would seem to show that the medical service given in the United States is at least from two to four times as effective as that in countries with sickness insurance.

Of course such a comparison is by no means wholly justifiable. Differences in age groups, in general social conditions, in wages, in general make up of populations, and in numerous other directions make any such absolute comparison impossible of accurate statistical statement. However, the difference is far too great to be accounted for by any of these elements. The one outstanding element present in Germany and England and absent in the United States is the method of giving medical service through insurance in the European countries and the method of private practice in the United States. The conclusion would seem to be justified that the major part of the increased days of recorded sickness is to be largely accounted for by the introduction of sickness insurance.

It may be responded at once that a large portion of this difference is due to the fact that the practicing physician in the insurance systems of Germany and England is required to certify to illness and that therefore this great increase in the amount of illness is largely accounted for by malingering. Physicians in these countries, who are the only ones capable of judging the character of the illness deny this. They admit that there is a certain amount of malingering but insist that a large proportion of this increase is due to the destruction of the will to get well by the encouragement which insurance offers to the creation and extension of disease. In other words, insurance creates a mass of disease and then aggravates this by an inefficient medical service.

It is a fair and just conclusion from all evidence available that the population in the United States which certain interests propose to include in any system of sickness insurance have today less sickness per person and recover from illness in a shorter time than those who are provided medical care through sickness insurance systems abroad. Moreover, the morbidity in the United States appears to be steadily declining, while it is increasing under sickness insurance systems. These facts are the only valid tests of the quality of medical service and justify the statement that private practice in this country is now supplying a service far superior to that which would be given under compulsory sickness insurance.

Should the Number of Professional Students Be Restricted?

RAYMOND WALTERS, LITT D Cincinnati This article
appeared in full in THE JOURNAL, March 30, page 1051

DISCUSSION

DR HAROLD RAPINS, Albany, N Y The number of medical students selected for training each year is influenced by three major factors the demand of the public for practicing physicians, the total facilities of the medical schools for training such physicians, and the supply of students In the forty years between 1890 and 1930, while the population of this country increased only 95 per cent the enrolment in secondary schools increased 1,520 per cent, and their graduates 1,360 per cent During the same period the student body of colleges and professional schools increased 660 per cent, with a rise of 770 per cent in college graduates The enrolment in colleges and universities has increased seven times, and in secondary schools fifteen times as rapidly as the population Just when this pressure of excessive numbers from below began to operate, it is difficult to determine However, it could not have been very great before 1926-1927 The fact that in that year there were over 20,000 multiple applications indicates a growing feeling on the part of the 8,500 eligible applicants that entering a medical school was no longer an easy matter Since 6,009 of these 8,500 applicants were actually enrolled that year the percentage of applicants who were rejected was only 29 The increasing percentage of applicants rejected in the succeeding years is shown as follows In 1926-1927 the number of applicants was 8,500, and 29 per cent were rejected In 1932-1933 the number of applicants was 12,128 and 45 per cent were rejected From 1926 to 1933 the enrolment has increased from 6,009 to 6,595 an increase of 586, or 97 per cent The increase in enrolment has, on the whole been permitted more for economic reasons rather than because there were adequate facilities for the training of that number of students In view of the fact that there is an apparently constant excess of approximately 100 per cent in the number of eligible applicants, this number can no longer serve as an effective guide for determining the number of students to be trained The present load is approximately 6,500 a year, and there is evidence that this is in excess of the number which the schools can properly handle The survey of medical schools should throw valuable light on the capacity of each school when the element of economic pressure is eliminated A fourth way to determine the number of students to be trained is by ascertaining how much "raw material" in the form of competent students the country yields This is difficult However, some light is thrown on the problem by the action of medical faculties in refusing to graduate a certain percentage of the students accepted In spite of the increasing requirements for admission to medical schools, promulgated between 1910 and 1920, and the increasing number of eligible applicants for admission to medical schools between 1920 and the present time, the total percentage of graduates in proportion to the total number of students is almost constant—approximately 22 Of 548 freshmen of the class which entered in 1911, 22.65 per cent failed to graduate,

while of 6,457 students entering in 1930, 23.1 per cent failed to graduate The fact that throughout this period there was almost a constant loss of 15 per cent before the beginning of the second year suggests that in the majority of these cases students were admitted who failed to demonstrate the ability to carry their studies to completion Since, of the 6,457 students who were selected for the class of 1930 from 13,569 eligible applicants, 14.2 per cent failed to complete the first year satisfactorily and 23.1 per cent failed to graduate, the conclusion appears inescapable that in spite of high standards of entrance and vigorous competition the country did not in that year produce as many satisfactory students as the number admitted for training It is reasonable to believe that a loss of 23.1 per cent under these selective conditions means that there are not enough qualified applicants and consequently that too high a proportion of unsuitable material is being accepted It is my opinion that this competitive selection has done more than raising preliminary educational requirements to speed up and intensify the intellectual pace of the medical undergraduate How far this reduction in numbers should be carried can best be determined when the report of the survey is before the committee There is already substantial evidence that some schools in this country are no longer maintaining proper educational standards and that other schools have temporarily lowered their standards by taking more students than they can properly train In the final registration of medical schools, each school should be registered for a maximum of freshmen commensurate with its facilities Such a limitation on each recognized medical school, plus the elimination of any schools no longer able to maintain proper educational standards, will go far to decrease the total number of students to a figure roughly equivalent to the number of qualified students the country can produce As a tentative estimate, it is suggested that by these means the total number of freshmen admitted each year in the future throughout the country would be approximately two thirds of those admitted at the present time On the other hand, the resultant decrease in the number of those admitted who fail to complete their studies should diminish the loss in time money and energy resulting from the present percentage of failures Perhaps from 75 to 80 per cent of the present number would graduate

DR WALTER L. BIERRING, Des Moines, Iowa The interesting survey by President Walters emphasizes that the oversupply of graduates in the different professions is a challenge to the educational forces at this time Comparing them with the graduates in medicine, it would seem that there are other professions in which this problem gives perhaps more concern than ours Attention should be directed to certain factors bearing on this question It is quite evident that within a generation, probably by 1960, there will be a balance of birth and death rates Again, by that time, or at least by 1980, the ratio will be about 1 to 690 It requires no special actuarial philosophy to determine how that will affect medical practice I think the element that perhaps is not considered is the distribution of physicians, which certainly is a factor in the practice of medicine, more marked than in the practice of law or other professions The study that is now being made by the Bureau of Medical Economics of the American Medical Association is going to give some information which will be most valuable, that there are communities where the ratio can be much larger and still furnish adequate medical care It should also be remembered that there is a strong tendency toward extending medical service in many directions It has been well mentioned that in engineering there is a marked extension into many fields of activity, so in medicine It is hoped that there may be other opportunities for medical service that will, to a certain extent, solve this problem There is also no question that in the regulation of specialism a certain part of the solution will be found, and that again the training of that general practitioner or family doctor who will probably carry on 85 per cent of the service required will be different He will have a better educational background, which will bring out that quality of service to which President Walters referred Certainly, these are the directions for the immediate future in the development of a higher grade of practicing physician, the limitation of specialism and perhaps a better study of the distribution of physicians, which will bring the solution, to a certain extent

The History of Medical Licensure

DR HENRY E. SIGERIST, Baltimore This article appeared in full in THE JOURNAL, March 30, page 1057

DISCUSSION

DR IRVING S. CUTTER, Chicago I shall attempt to add but a few words to Dr Sigerist's scholarly paper in relation to medical licensure in America. The reason for the first move in New York State in 1760 is found in the preamble of the law that was passed, namely, that the community was overrun with quacks and charlatans. The preamble states that there were something like sixty practitioners of medicine or gentlemen of the faculty, as they were called in the city and not more than five or six had been bred physicians, and by that phrase was meant had graduated from some reputable medical school. Strangely enough, the New York committee that conducted the examination contained no medical men. They were men who were the aldermen or clerks of committees of the city government, and any one of the judges could be members. So generous was the supply of quacks throughout the colonies that Samuel Sterns, a physician who practiced also in Massachusetts and Vermont whose sister, by the way, was the wife of the astronomer Herschel, said he made a canvass of the physicians with whom he came in contact in Massachusetts and Vermont and could find only three out of some forty or fifty who possessed any copy of Rush's work, Birtinns botany, Culloms nosology, the London Pharmacopoeia or Lewis's Materia Medica, from which he concludes that there is a very great dearth of medical knowledge in the state. When N. S. Davis wrote the delightful story about medical education that was published in Chicago just eighty-five years ago, he made a plea that medical licensure might be utterly divorced from medical teaching. He felt that medical licensure in this sense would have a check on medical teaching, largely because of the tremendous number of low grade medical schools then in the country. For many years before and after 1844 a diploma from any sort of medical school admitted to medical practice. It wasn't until the nineties that there were even twelve states that required a separate examination. In some states, all that was necessary was to file a certificate from a medical society or a medical school or from a practitioner of medicine that the individual was of good moral character. There was no other certification required. In the early nineties, Reginald Fitz, to whom we owe so much in our knowledge of appendicitis, wrote a series of articles that were published in the *Boston Medical and Surgical Journal*, giving the history of medical licensure in America. Chasing down from that I ran across some items in *Northwest Medicine* in the early nineties giving a series of questions and answers of successful candidates before state board examinations as conducted at that time. I am going to read two or three of them. "What is scrofula?" "The scrofulous diathesis is a peculiar, greasy exudation from the axilla or inside the thighs, possibly behind the ears. It has a sour, fetid and strong smell." "What are the symptoms of cardiac dilatation?" "A feeling of water in the bowels, loss of flesh. The treatment is to put the patient on a milk diet, give rectal enema and pepsinical food, also a nerve tonic to build up the system." Of course, the tremendous improvement between those days and the present days needs no emphasis, but lest the present members of the state boards have an undue pride of possession in their achievements, I must relate a story told by one of our graduates. He called on a state board in a neighboring state not long ago and found the chairman of the board engrossing in a large book death certificates, enumerating the causes of death. When the student asked about his position in the examination, without giving a categorical answer he said to the student, "Darn these doctors anyway. They can't write. Just look at this death certificate." And there written plainly, indeed, were the words "Bacillus aerogenes capsulatus." The student said, "Why, that is clear. That is Bacillus aerogenes capsulatus, that is gas bacillus." "Oh, sure," he said, and down went as the cause of death 'gastritis'."

The Larger Social Aspects of Medical Education

DR. WILLARD C. RAPPLEYE, New York The sweeping changes in economic and social affairs in this country and the increasing influence and power of the government to regulate every phase of activity and policy are bound to have an impor-

tant influence on the role that the medical profession is to play in the present and future social order. The functions to be performed by the profession and the demands that may be made on it will have far reaching effects on the character of medical education.

The primary purpose of medical education is to provide the community with properly trained personnel to carry out an adequate program of medical service. Medical care has always been a function of society. The forms that it has taken have followed closely the shifting changes in the social structure. Specialization, for example, was well recognized in Egypt in 2500 B. C. Codes governing medical practice have existed from the days of Hammurabi, whose code in 2250 B. C. prescribed the conditions under which physicians practiced and a schedule of fees they might charge. Long before the Christian era, physicians in Greece were employed by the state. In the Middle Ages the education of the physician and the methods of protecting the public from untrained practitioners were established on a basis that has seen little change for 800 years.

Even the economic and social factors of medical care with which we are so much concerned at the moment had their beginnings in antiquity. In ancient Rome, mutual aid associations existed and regulations were made for the conduct of practice and the financial arrangements of the physicians. From the very beginning two important economic aspects of medical care were recognized, namely, the uneven distribution of the financial burden of sickness and the unpredictability of its character or severity for the individual. Many devices were created to spread the financial risks involved in sickness, but the first attempt to formulate a solution on a national basis was made in the French convention of 1794. Following this a great number of societies were organized in an endeavor to provide group protection. In his imperial message to the reichstag in 1881, Bismarck outlined the responsibility of the government in relation to this whole problem. Out of his message grew the compulsory sickness insurance program of Germany, which became effective in 1883. Most leading countries of the world have now adopted some form of collective protection for sickness.

In every country in which provisions for sickness insurance have been made the programs have been identified with the political institutions of the country. It is probably more because of this fact than any other that there is great hesitancy on the part of medical leaders to sponsor and support programs for sickness insurance here. There is a lack of confidence on the part of many people in the local political institutions as they exist in many of our communities. The real problem is to create methods of delivering medical services of a high quality to the entire population and to devise programs by which the quality of that care may be continued. The danger in most schemes developed by lay and political groups is that the quality of medical care is gradually sacrificed for nominal performance and mediocrity. This has been the experience in most countries of the world. A sound program of medical care for the country cannot be maintained by graduating and licensing an excess number of physicians. An oversupply of physicians leads to unnecessary services, to a lowered quality of care, and to excessive costs because the individuals are not able to judge their needs in such a highly technical field as medicine. The Council on Medical Education and Hospitals, the Association of American Medical Colleges and the Federation of State Medical Boards are now engaged in a study of the larger objectives of medical education and a reclassification of medical schools in an effort to improve the quality of training and to bring about a further elevation of the level of practice. The great need of the country is for better not more, physicians and for opportunities for those in practice and those who are qualified to specialize to prepare themselves adequately for their responsibilities to the public.

The public is confused by the large number of doctors who claim to be specialists whereas in reality there is a real shortage of properly trained experts in the various fields to meet the needs. Opportunities and facilities are quite inadequate for the training of a sufficient number of properly qualified specialists, although the number of hospitals in which such training may be given is sufficient if educational supervision and direction can be secured.

There are indications that there will soon be developments in graduate medical education that will be as far reaching and

vital to the public welfare as that which has been witnessed in undergraduate training, the last two or three decades. Perhaps the most important factor in all these programs is the mobilization of hospital and clinical facilities, which will make the resources of these various institutions available. The extensive hospital facilities of high quality found in every section of the country offer a unique opportunity and responsibility in the field of graduate education, which at the moment is the weakest link in the medical program of the country. If wisdom is to be utilized in the formulation of a program of medical service for the country, that program must not be planned and governed only from the economic aspects or on the basis of the present economic crisis alone. Not only must a well considered program for the future provide for the distribution of the economic burden of sickness and for the preservation of a high quality of medical care, but it must also create the opportunities and incentive to attract increasing numbers of superior students to enter the career of medicine.

Most of the propaganda in this country on the social aspects of medicine have been governed largely by the experiences in Europe where sickness insurance was really a political accident and was given its direction of development before the knowledge and facilities necessary for modern medical services existed. It probably is true that most of our population when employed do not need sickness insurance for the usual illnesses and the services of a general practitioner which are the basic features of the European plus of social medicine. The large economic hazard is for hospital care of which a larger proportion of professional services are those of specialists. The cost of hospital care is a large item in the total cost of medical services, but the burden from this source falls on less than 5 per cent of the population. The costs of hospital services are the largest and most unpredictable features of medical care. A plan for the adequate support of the hospitals of the country and the reasonable compensation of physicians on their staffs for the professional care of the indigent patients in their wards and outpatient services and the employment of physicians to care for the indigents in their homes for whose care the community must assume responsibility would go a long way to solve the economic factors of medical care in this country.

Not only does the hospital represent a base of operations for all forms of community medical service but it has a type of organization that can readily be amplified to include cooperation in home nursing and home medical service through its outpatient service and other channels and it also has the most satisfactory type of organization to preserve high standards of professional performance. The 126,261 physicians now on the staffs of the hospitals represent a large army of doctors who are organized and for the most part ready to participate in a broad community health service and to carry on graduate medical education. Considering the entire problem of sickness, the adequate financing of hospital services alone, through funds from taxation, so called hospital insurance, philanthropy and earnings, and the amplification of the present functions of such institutions would largely solve the most pressing economic problems of medical service in this country. There is little doubt that the country is entering a new phase of national policy characterized by collectivism, cooperative enterprise and an increasing degree of governmental control and planning. It is not necessary that an accurate prediction should be made of the exact forms which medical services of the future are to assume. I believe however that a sound training in the fundamental biologic sciences must continue to be the basic preparation of the student because the principles of those sciences undoubtedly will form the foundation of medical practice, preventive medicine and public health work of the future. The training should emphasize however that the methods by which these principles are to be applied in meeting the needs of individuals in the community are likely to be modified in the future. Students must be prepared psychologically and with a certain amount of special information to meet the shifting social and economic phases of medical care. It is the responsibility of physicians to mobilize their knowledge and skills so that the rich heritage from past generations may be utilized to the fullest benefit of contemporary society.

(To be continued)

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be as follows:

April 11 Sickness Insurance R. G. Ireland, M.D.
April 18 Catarrh W. W. Bauer, M.D.
April 25 May Day or All Year Round? W. W. Bauer, M.D.

National Broadcasting System

The American Medical Association broadcasts under the title 'Your Health' on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

April 9 Crying for the Moon W. W. Bauer, M.D.
April 16 Meeting a Challenge W. W. Bauer, M.D.
April 23 Sudden Death Morris Fishbein, M.D.

Medical News

(PHYSICIANS WILL CONFERR A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARKANSAS

State Medical Meeting at Fort Smith—The sixtieth annual session of the Arkansas Medical Society will be held at Fort Smith, April 16-17, with headquarters at the Goldman Hotel, under the presidency of Dr. Fergus O. Mahony, Li Dorado. The program will include the following physicians:

Walter L. Biering, Des Moines, president American Medical Association
The Functions of the American Medical Association
Samuel E. Thompson, Kerrville, Texas, Diagnostic Problems in Diseases of the Lungs
William B. Grayson, Little Rock, The Problem of Malaria
Arthur C. Sullivan, Hot Springs, National Park, Use and Abuse of Digitals
Harvey D. Wood, Fayetteville, Vaginal Hysterectomy with the Original Pryor Clamp
J. H. Eugene Rosamond, Memphis, Tenn., Appendicitis in Childhood
Lucian H. Landry, New Orleans, Cicatricial Stenosis of the Esophagus
Lee Vallette, Farmley, Little Rock, Fractures About the Elbow
Eugene M. Smith, Hot Springs, National Park, Underwater Therapy in the Treatment of Chronic Arthritis (motion picture)
Merlin J. Kilbury, Little Rock, A Review of 300 Cases of Breast Tumors
Paul A. O'Leary, Rochester, Minn., Types of Neurosyphilis Benefited by Malaria Therapy
Ralph Bowen, Oklahoma City, Practical Management of the Asthmatic Child
Ralph A. Ray, Chicago, Recent Advances in Gynecology
Herbert Fay II, Jones and Thomas, Duell, Brown, Little Rock, Further Studies in Prostatic Resection
Frank P. Hardy, Center Hill, Hysteria in General Practice
Howard A. Dishongh, Little Rock, Uduulant Fever
Robert H. Hood, Russellville, Management of Pertussis
George V. Brindley, Temple, Texas, Cancer of the Rectum, Factors Affecting Its Cure (motion picture)
John M. Smith, Russellville, Gollier (motion picture)
Ernest Hart White, Little Rock, Bands & Rings
Oscar J. T. Johnston, Batesville, Femoral Hernia with Unusual Contents
Molt S. Dohrell, Van Buren, Malaria
Pat Murphy, Little Rock, Vertigo

An evening session will be addressed by Dr. Biering on "The Doctor and Plans for Economic Security," and Mrs. Rogers N. Herbert, Nashville, Tenn., president Woman's Auxiliary, American Medical Association, "The Woman's Auxiliary and the Medical Profession."

COLORADO

Bills Introduced—H. 634 proposes to require all applicants for licenses to practice any form of the healing art before presenting themselves to their respective professional boards for examination to pass examinations in anatomy, physiology, chemistry, bacteriology and pathology, to be given by an impartial board of examiners in the basic sciences. The members of the board of examiners in the basic sciences are to be selected because of their knowledge of the basic sciences and each member is to be on the faculty of the University of Colorado, the Colorado State Agricultural College, the Colorado School of Mines or some other institution of learning in the state of equal rank. No member of the board is to be engaged in the practice of the healing art during his term of membership. H. 949 proposes to reorganize and consolidate the public

health agencies of the state and counties by establishing a state department of health, county boards of health and local health districts. H 668 proposes to create a board of examiners of drugless physicians and to regulate the practice of drugless physicians. "Drugless Physicians' practice" is defined as "the Science locating and removing interference with nerve transmission, and freeing the Human body of abnormal conditions, and the employment and practice of Physio-Therapy, Electro-Therapy, Naturopathy, and Hydro-Therapy, Neuropathy, Mechano-Therapy [sic], Manipulation and such other drugless practice including Hygienic and Sanitary measures necessary to such practice." Such licentiatees are not to be permitted to practice surgery or to administer drugs, but they are to be permitted to make and sign birth and death certificates.

DELAWARE

Bill Passed—Substitute for House 310 has passed the House. It purports on its face to amend the law requiring the payment of certain occupational taxes. It requires that before a person engages in any "service" occupation listed in the bill he apply to the clerk of the peace for a license to do so and pay an annual fee of \$10.50. The bill then provides that "every individual who shall procure a service occupation license shall be authorized and empowered during the term for which such license was granted, to exercise and carry on such service occupation." Before a physician or an osteopath may procure this occupational license he must be "qualified under the law of the State to practice." A chiropractor, however, need not be qualified under the laws of the state to practice before applying to the clerk of the peace for an occupational license, but when he obtains his occupational license, without proving in any way his moral fitness or other qualifications, he seems under this bill to be fully authorized to practice, so long as the occupational license is in force.

DISTRICT OF COLUMBIA

University News—Elmer V. McCollum, Ph.D., professor of biochemistry, Johns Hopkins University School of Hygiene and Public Health, Baltimore, delivered the fourth lecture in the Smith-Reed-Russell series at George Washington University School of Medicine, March 5, his subject was "The Role of the Vitamins in Relation to the Bodily Resistance to the Infectious Diseases."

Medical Bills in Congress—S 2013 has been reported to the Senate, directing the Commission on Licensure to Practice the Healing Art in the District of Columbia to issue a license to practice the healing art in the District of Columbia to Dr. Pak Chue Chan (S Rept. 390). S 2153 has been reported to the Senate, providing for the prevention of blindness in infants born in the District of Columbia (S Rept. 391).

ILLINOIS

Bills Introduced—H 676, to amend the workmen's compensation act, proposes that an employee suffering a hernia as a result of an industrial accident have the right to choose either suitable mechanical correction or surgical treatment. If he chooses mechanical correction, he is to be permitted to decide what mechanical appliance and service shall be furnished him and the employer must furnish the appliances during the employee's lifetime. However, within ninety days after the employee has selected mechanical appliances he is to be permitted to revoke his selection and elect, at his employer's expense, to submit to surgery. H 692, to amend the medical practice act, proposes, in effect, to require the department of registration and education to appoint a committee of osteopaths to examine the medical practitioners who practice osteopathy and the medical practitioners who practice both osteopathy and medicine in all of its branches.

Chicago

Northwestern Faculty Presents Program—Members of the faculty of Northwestern University School of Medicine presented the program before the Chicago Medical Society, March 27. Drs. Merritt Paul Starr discussed "Studies of the Thyrotropic Pituitary Hormone," Michael L. Mason, "Immediate Treatment of Injuries," M. Herbert Barker, "The Blood Cyanates in Cyanate Therapy of Hypertension," and Charles Marshall Davison, "An Evaluation of the Relative Merits of Cholecystectomy versus Cholecystostomy."

Corporate Practice of Medicine Illegal—A corporation cannot legally practice medicine in Illinois, even though it assumes to do so through physician-employees according to the decision of Judge M. L. McKinley, of the Superior Court, Cook County, March 22 in the case of *People of the State of*

Illinois, by Otto Kerner, Attorney General, v. United Medical Service, Inc. The United Medical Service, Inc., has been holding itself out to the public as undertaking through the agency of physician-employees to give medical service. The attorney general instituted suit to require it to show its authority for doing so. Judge McKinley's decision holds that the activities of the corporation are illegal. He entered a judgment ousting the corporation from "the franchise, occupation and business" of engaging in the diagnosis and treatment of human ailments. The corporation will appeal to the Supreme Court of Illinois. Pending the determination of the appeal, the judgment of ouster will stand suspended.

Judge Holland Imposes Minimum Sentence on Quacks—The Illinois State Department of Registration and Education has been conducting an investigation of some alleged quacks with regard to violations of the state medical practice act. Among those investigated were:

Doe J. B. Adams, 162 North State Street
Dr. George Leo Curran, 334 South Clark Street
Mrs. Mary Dunn, 233 West Adams Street
Mrs. Rose Parker, 2531 West Monroe Street
Madame J. B. Colay, 2937 Ellis Avenue
Rev. Frederick J. Harris, 3014 Lake Park Avenue who it is reported said "I've healed many a person with cancer and tumors or diabetes or paralysis after the doctors gave up hope for them."
James J. O'Donovan, 1203 North Dearborn Street
Yogi Roy, 2110 North Clark Street
Dr. Robert A. De Isle, unlicensed chiropractor who is said to have been fined \$150 in San Diego, Calif. in 1925 and placed on probation for one year on a charge of practicing medicine without a license.

The investigation has resulted in the trial and conviction for practicing medicine without a license of James P. O'Donovan, Frank H. Vlock and Yogi D. Roy, each of whom was assessed a fine of \$100 and costs. The futility of endeavoring to stop quack practices by imposing the minimum penalties provided by law was expressed in an editorial in the *Chicago Tribune* March 26, in part, as follows:

Recently Municipal Judge Eugene J. Holland completed the trials of three quack doctors brought before him by the state department of registration and education and imposed upon them the minimum penalties provided for practicing medicine without a license—fines of \$100 each.

After pronouncing the minimum sentences (which the defendants are appealing) Judge Holland had the temerity to praise his own findings as deterrents to the continued illegal practice of medicine. They were no such thing. The publicity given the activities of the three fakers may have warned the public against them but the judge had nothing to do with that.

His fines merely have the effect of declaring the state in on the illegal and shameful profits of the trio. They smack of the hypocritical practice which some communities have of fining their prostitutes and gamblers at regular intervals thus collecting an extralegal license fee on illegal business.

IOWA

Personal—Dr. Walter A. Sternberg, Mount Pleasant, has been appointed a member of the state board of health, succeeding Dr. Nathaniel M. McKitterick, Burlington, resigned.

Bill Introduced—H 428 proposes to create a state board of eugenics which may on the application of the patient or his guardian authorize sexual sterilization if there are "reasons to believe that reproduction or further reproduction would produce offspring which because of physical or mental unfitness would become a burden or menace to the State."

Society News—At a meeting of the Southwestern Iowa Postgraduate Society in Shenandoah, February 13, speakers were Drs. H. Winnett Orr, Lincoln, Neb., on "Diagnosis of Rare Back Injuries," Arbor D. Munger, Lincoln, "Problems in Prostatic Disease" and Erwin J. Gottsch, Shenandoah, "True Surgery of Gas Gangrene Infection."—Dr. Emil Novak, Baltimore, addressed a special meeting of the Des Moines Academy of Medicine and the Polk County Medical Society March 14 on "The Endocrine Aspects of Sterility." Speakers before the society, February 26, included Drs. Harry C. Willett on "Verruca—and a Review of the Therapy," Harry A. Collins "Postoperative Atelectasis" and David M. Blum, "Food Allergy in Relation to Migraine and Abdominal Symptoms."

KANSAS

Society Changes Name—At a meeting in Norton, in February, the name of the Decatur-Norton County Medical Society was changed to the Northwest Kansas Medical Society. Dr. Charles F. Taylor, Norton, newly elected president discussed diagnosis of tuberculosis. Two papers were presented by Dr. Charles O. Giese, Colorado Springs, Colo., on "Pneumothorax in Lobar Pneumonia and Primary Carcinoma of the Lung." Tuberculosis was also discussed by Dr. Philip Cohn, Norton.

Society News—At a meeting of the Wyandotte County Medical Society March 6, Drs. Paul M. Krall and Fred E.

Angle, Kansas City, discussed electrocardiography in myocarditis and arrhythmias, respectively. — Dr Thomas G. Orr, Kansas City Mo., discussed "Treatment of Intestinal Peritonitis" before the Sedgwick County Medical Society, March 5.

LOUISIANA

Tuberculosis Institute — Sponsored by the Tuberculosis and Public Health Association of Louisiana and the Tuberculosis Committee of New Orleans, a tuberculosis institute was held March 29, in New Orleans. In the evening the session was combined with a special meeting of the Orleans Parish Medical Society, speakers were Drs Jay Arthur Myers, Minneapolis on "The Evolution of Tuberculosis in the Human Body" and Gunnar Nyström, professor of surgery, University of Uppsala, Sweden, pulmonary embolism.

MAINE

Bill Introduced — H 1772 proposes to prohibit the sale or other distribution of any cosmetic preparation not registered with the department of health and welfare in accordance with the department's regulations. The department is to be authorized to refuse to register any cosmetic preparation which in its judgment contains injurious substances in such amounts as to be poisonous, injurious or detrimental to the person.

Bill Passed — S 651 a redraft of S 241, has passed the house, proposing to amend the medical practice act by authorizing the revocation of the license of any licentiate who (1) has been convicted, either within or without the state, of any crime involving moral turpitude or of any crime in the practice of his profession (2) has been guilty of fraudulent or unprofessional conduct in the practice of his profession (3) is addicted to the use of narcotics or (4) has used advertising which the board of medical examiners considers to be deceptive, misleading, extravagant, improbable or unethical.

Society News — At a meeting of the Kennebec County Medical Association in Augusta February 21, speakers were Herbert E. Locke, attorney, Augusta, and W. T. Bove, Ph.D., Colby College, Waterville, their papers were entitled "Some Practical Aspects of Medical Jurisprudence" and "Debt of Science to the Physician," respectively. — The Knox County Medical Society was addressed, recently, by Drs Howard L. Apollonio, Camden, on "Fracture of the Femur," C. Harold Jameson, Camden "Polycystic Kidney Disease," and Edwin W. Gehring, Portland, president, Maine Medical Association, "Birth Control and Disease Prevention." — Dr Louis C. Planteuf, Boston discussed cervical cesarean section before the Cumberland Medical Society, Portland, February 28.

MARYLAND

Bill Passed — H 145 has passed the house and the senate, proposing to prohibit the retail sale and distribution of barbitol and other hypnotic and somnifacient drugs except on the prescription of a licensed physician, dentist or veterinarian. The drugs mentioned are to include barbituric acid, sulphonethylmethane (trional), sulphomethane (sulphonol), diethylsulphon diethylmethane (tetronal), paraldehyde, and chloral or chloral hydrate or chlorbutanol.

Bills Introduced — H 536 proposes to authorize the sexual sterilization of incurable idiots, imbeciles or morons. H 547, to amend the osteopathic practice act, proposes to permit osteopaths to make and sign death certificates. H 560 to amend the workmen's compensation act, proposes to define "injury" and "personal injury" [which is compensable under the act] to "include, in addition to injury by accident occupational diseases, and any disease growing out of, incident to, or proximately caused by, the employment."

MICHIGAN

Outbreak of Streptococcal Sore Throat — About twenty-five cases of streptococcal sore throat with one death were recently reported in Bronson. On investigation, several cows in the herd supplying the milk in question were found to have mastitis. According to the state medical journal an encapsulated organism corresponding in every way to Streptococcus epidemicus was isolated from the milk. The organism is of human origin. It was not recovered from the throats of patients, but, the journal states, there seems to be abundant evidence to conclude that the outbreak was milk borne and caused by the hemolytic Streptococcus epidemicus. The milk was not pasteurized.

Bills Introduced — S 289 proposes to bring within the purview of the narcotic drug act barbituric acid derivatives and compounds, sulphonethylmethane (trional), sulphomethane (sulphonol), diethylsulphon diethylmethane (tetronal), carbonyl,

paraldehyde and chloral or chloral hydrate or chlorbutanol. H 252 proposes to prohibit the employment of any person, in a state hospital for a period longer than an average of nine hours a day, or fifty-four hours in any week, or more than ten hours in any one day. H 381 proposes to grant charitable and governmental hospitals treating persons injured through the fault of others liens on all rights of action, claims, judgments, compromises or settlements accruing to the injured persons by reason of their injuries. H 393, to amend the workmen's compensation act, proposes, in effect, to make occupational diseases compensable. H 401, to amend the workmen's compensation act, proposes to forbid physicians to receive for services and expenses in any case arising under the act fees in excess of 10 per cent of the amount of compensation allowed the injured workman. However, in cases in which the compensation allowed does not exceed \$500, physicians fees may not exceed 20 per cent. H 428, to amend the workmen's compensation act, proposes that all hernias arising out of and in the course of employment shall be conclusively presumed to be accidental and that the employee be entitled to compensation for twenty weeks. If an employee accepts an operation tendered by the employer and the operation is unsuccessful, the employee is to be entitled to receive compensation as for other disability. H 427, to amend the workmen's compensation act, proposes that during the first ninety days after an industrial injury the employer is to furnish necessary medical, surgical and hospital services and medicines to the injured employee. After the expiration of that time the compensation board is to be authorized to direct the employer to furnish additional medical, surgical and hospital services. S 281, to amend the osteopathic practice act, proposes (1) to dub the Michigan State Osteopathic Association "the Michigan State Osteopathic Association of Physicians and Surgeons," (2) to permit the secretary of the board of osteopathic examiners to receive such salary as may be fixed by the board and to employ such assistants and investigators as he deems necessary, (3) to raise the examination fee required of applicants for licenses to practice osteopathy to \$35, and the fee required of applicants for licenses on the basis of reciprocity to \$75, (4) to require osteopathic licentiates to register annually with the board and to pay an annual fee of \$10, (5) to make it a condition precedent to annual registration that the licentiate has attended at least one of the two-day "education programs" as conducted by the "Michigan Osteopathic Association of Physicians and Surgeons" and (6) to provide additional grounds for the revocation of licenses.

MINNESOTA

Bills Introduced — S 1319 and H 1408 propose to authorize the county board of any county to provide for the hospitalization, in hospitals within the county or elsewhere within the state, of indigent persons afflicted with a malady, deformity or ailment of a nature which can probably be remedied by hospitalization. H 890, to amend the workmen's compensation act, proposes to make poisoning by carbon monoxide fumes or its sequelae compensable.

Dr Blumenthal Will Give Vander Horck Lecture — The second annual Vander Horck Lecture of the Minnesota Dermatological Society will be delivered, April 18, by Dr Franz Blumenthal, research professor of dermatology, University of Michigan Medical School, Ann Arbor. His subject will be "The Paradoxical Influence of the Sun's Rays on Cancer, Causative and Curative." These lectures were initiated last year in memory of Dr Max P. Vander Horck, who died in 1911.

NEW HAMPSHIRE

Personal — Dr Arthur W. Hopkins, West Swanzey, was guest of honor at a dinner given by the town board of education, teachers and other citizens, January 29, in recognition of his twenty-five years of service on the board. — Dr Robert B. Kerr, Manchester, was recently appointed a member of the state board of public welfare.

Dr Watson is a former president and secretary of the Obion County Medical Society.

State Medical Meeting at Nashville—The one hundred and second annual session of the Tennessee State Medical Association will be held in Nashville, April 9-11 with headquarters at the Noel Hotel and under the presidency of Dr John O Manier Nashville. Guest speakers will be Drs Henry Kennon Dunham Cincinnati, Lay Martin Baltimore, Alexander J Kotkis St Louis, Austin A Hayden, Chicago. Among Tennessee physicians listed on a tentative program are

Dr Lucius C Sanders Memphis Physical Reactions to Functional Disorders
Dr Jesse Lawrence Cochran Jackson Botulism
Dr Gideon W Stone Knoxville Version Its Indications and Advantages
Dr Charles Roberts Thomas Chattanooga Some Neurologic Manifestations of Hypertension
Dr John B Haskins Chattanooga Extraperitoneal Pathology with Intraperitoneal Symptoms
Dr Milton Smith Lewis Nashville Management of the Occipital Posterior Position

The Tennessee State Pediatric Association will meet April 8 with Drs Philip F Barbour Louisville Ky and J Norman Henry, Philadelphia, as guests. The Tennessee Academy of

Ophthalmology and Otolaryngology also will meet, April 8, with Dr Walter S Lawrence, professor of roentgenology, University of Tennessee College of Medicine, Memphis, as guest speaker, on "Results of X-Ray and Radium Treatment in Certain Diseases of the Eye".

UTAH

Bill Enacted—H 211 has become a law, repealing the laws regulating the sale, distribution or possession of narcotic drugs and enacting what apparently is the uniform narcotic drug act. The term 'narcotic drug,' as used in this law includes coca leaves, opium, cannabis and every substance neither chemically nor physically distinguishable from them. A physician or a dentist, acting in good faith and in the course of his professional practice only, may prescribe, administer and dispense narcotic drugs or he may cause them to be administered by a nurse or intern under his direction and supervision. Physicians and dentists are to keep a record of narcotic drugs received by them and a record of all such drugs administered, dispensed or professionally used by them otherwise than by prescription.

WASHINGTON

Annual Surgical Clinic—The Puget Sound Surgical Society held its annual surgical clinic and banquet in Seattle, March 23. Dr Verne C Hunt Los Angeles, conducted clinics at the King County Hospital during the day, and the banquet was held at the Rimmer Club in the evening. Dr Hunt spoke on 'The Opportunities in Surgery' and Dr Kenneth L Partlow, Olympia, 'Modern Conception of Medical Costs in Washington'.

WISCONSIN

Bill Introduced—A 517 proposes to amend that section of the medical practice act forbidding any person not possessing a license to practice medicine and surgery, osteopathy or osteopathy and surgery to use any title or designation which represents him 'as a doctor in any branch of treating the sick' by permitting a licensed chiropractor to use the title of 'Doctor of Chiropractic,' or 'D C'.

CANAL ZONE

Dr Louis N Smernoff license revoked as of Dec 18 1934 for having performed an illegal operation. His present address is not known.

FOREIGN

Prize for Essay on X-Rays—The David Anderson Berry Gold Medal with a sum of money amounting to about £100 will be awarded in July by the Royal Society of Edinburgh to the person who in the opinion of the council has recently produced the best work on the nature of x-rays in their therapeutic effect on disease in human beings. The secretary of the society is James H Ashworth, D Sc 22 George Street Edinburgh 2.

International Hospital Meeting—The fourth International Hospital Congress will be held in Rome, May 5-12. Following are the subjects of discussion announced: the hospital as a link in a systematic public health service, equipment and technical appliances of the hospital, function and protection of the hospital in times of national calamity, and importance of each main group of the hospital staff with regard to the relations of the hospital to the community. The congress will be preceded by a study trip through Milan, Turin, Genoa, Florence and Piesole. Details of the congress may be obtained from the headquarters of the International Hospital Association, Cantonal Hospital, Iuzerne, Switzerland.

Fifteenth International Physiological Congress—Plans for the fifteenth International Physiological Congress to be held in Leningrad and Moscow, August 9-18, have been announced. The congress will meet first in Leningrad, August 9-17 go to Moscow overnight and hold its final sessions in Moscow, August 18. Prof Ivan P Pavlov, Leningrad, is president of the congress committee. An American delegation will sail from New York July 25 on the S S *Berengaria*. A stop will be made in London, where members may attend the International Neurological Congress, July 29-31, if they wish. Various tours to other parts of Russia have been arranged, of which details may be obtained from Intourist, Inc., 545 Fifth Avenue New York. Information concerning the program may be obtained from the Organization Committee, International Physiological Congress, Main P O Box 13, Leningrad, U S S R.

Society News—An All-Russian Congress for Physical Therapy will be held in Odessa August 22-25, with the following subjects for discussion: physical therapy in relation to allergy, acute infectious diseases, sequelae of injuries and the vegetative nervous system, and short wave therapy. The third International Air Ambulance Congress will be held in Brussels Belgium, June 11-16. The first congress was held in Paris in 1929 and the second in Madrid in 1931. The International Association for Prevention of Blindness held a general assembly in London April 5 during the Congress of the Ophthalmological Society of the United Kingdom, with discussions of international classification of the causes of blindness and hereditary diseases of the eye ending in blindness. The World Federation of Education Associations will be held August 10-17, in Oxford England. The German Roentgen Society has erected a memorial tablet to Wilhelm Konrad Roentgen, discoverer of the roentgen ray on Roentgen Road in the Engadine where he spent his vacations. The National Association for Prevention of Tuberculosis of England will hold its twenty-first annual conference at Southport, June 27-29. The subject for discussion will be 'The Responsibility of the Nation Toward the Child in Respect of Tuberculosis.'

Deaths in Other Countries

John James Rickard Macleod, co-winner of the Nobel Prize in Medicine in 1923 and since 1928 regius professor of physiology at the University of Aberdeen, Scotland, died, March 17, at his home in Aberdeen, aged 58. Dr Macleod was born in Cluny near Dunkeld, Scotland Sept. 6, 1876. On graduating from the University of Aberdeen Faculty of Medicine in 1898 he was awarded the Anderson Traveling Scholarship and from 1898 to 1899 he studied at the Physiological Institute of Leipzig University. He was appointed a demonstrator of physiology at the London Hospital Medical School in 1900 and in 1902 lecturer in biochemistry. In 1902 he obtained a diploma in public health from Cambridge University. He was appointed professor of physiology at the Western Reserve University, Cleveland, in 1903, which position he held until 1918, then he was professor of physiology and associate dean at the University of Toronto Faculty of Medicine serving until 1928, when he was invited to become regius professor at his alma mater. He received honorary degrees from the universities of Toronto, Aberdeen, Western Reserve, Pennsylvania and Jefferson Medical College. He was president of the American Physiological Society in 1922 and in 1925 president of the Royal Canadian Institute. He was a member of scientific societies in the United States, Canada and Great Britain and a corresponding member of German and Italian societies. From 1929 to 1933 he was a member of the Medical Research Council of Great Britain. Dr Macleod was the author of a long list of publications on physiologic subjects, especially carbohydrate metabolism, lactic acid in the blood and the control of breathing. The work for which he was most widely known was done in association with Banting and others in the development of insulin for which he and Banting were awarded the Nobel Prize in physiology and medicine in 1923. He was awarded the Cameron Prize of the University of Edinburgh in the same year.

March 16, 1935

The Workmen's Compensation Acts Prolong Disability

The report of a committee appointed by the British Medical Association to consider the treatment of fractures has been reviewed in a previous letter. An appendix on "Nonmedical Factors of Prolonged Disability" was not included and because of its importance, requires a special notice. While disclaiming that a purely medical committee can have an intimate acquaintance with all aspects of the fracture problem, the committee felt that some reference was necessary to the nonmedical factors that militate against return to work. The committee points out that the workmen's compensation acts in many cases play a powerful part in prolonging disability and delaying return to work and on occasion in converting the workman into a permanent invalid. The committee freely admits that the acts are humane and beneficial. That legislation in other countries has been based on them shows that the ideas conceived in this country are sound. But the acts contain no provision for the rehabilitation of the man after injury and place no liability on him to prove that he has sought and obtained efficient treatment, while the type of monetary benefits granted under the acts are often positively harmful to the man. Three methods are adopted by employers for insuring against the liabilities imposed on them by the workmen's compensation acts: (1) through insurance companies, (2) by mutual associations of groups of employers, and (3) by individual employers. Under the first method the insurance company is not concerned with the man's recovery as such but with the settlement of his claim as speedily as possible. Measures such as those recommended by the committee to reduce the periods of incapacity in general will not necessarily be welcomed by the companies, as they must eventually involve a reduction of revenue through lowering of premiums. On the other hand, the second and third methods have not this disadvantage. The economic advantage of the insurers is implicit in the recovery and ultimate welfare of the disabled man. For this reason mutual associations and self-insured employers often find it advisable to employ their own medical officer to supervise the injured workman. An admirable scheme, recognized under the compensation acts, is under the control of a board composed partly of employers and partly of workmen. It allows for the provision of unbiased medical referees whose opinion is final and is accepted without litigation by all parties. It also arranges for lump sum payments and pensions.

LIGHT WORK

One of the main difficulties is the return of the convalescent man to work suitable for his physical condition. A man convalescent from a fractured leg will not be unfit for ordinary work one day and fit for it the next. There must be a period when he becomes fit for light work and when he would be materially benefited by it. Large employers should earmark certain forms of occupation suitable for convalescent men. But in the present industrial conditions there are almost insuperable obstacles to the provision of such light work apart from large employers. With so much unemployment today there often appears a tendency to nurse invalidity as an alternative means of subsistence.

LUMP SUM PAYMENTS

The compensation acts provide for weekly payments but also give the employer the right to commute by paying the redemption value, which is a sum fixed by the act. The

employer and the workman can also agree to a lump sum, subject to the approval of the court. The lump sum form of compensation is responsible for much prolongation of disability. The prospect that a sum considerably larger than any he has been accustomed to handle may eventually be obtained if the applicant is persistent and patient enough is sufficient in many cases to deter him from seeking or even desiring to recover completely. Further, to return to work before the settlement of the claim would probably result in diminution of the amount of the lump sum. Touts from solicitors actually wait on the victims of accidents to promote litigation. It is not surprising that, until the compensation claim is settled, the workman's attention is focused on his financial prospects rather than on his restoration to full activity. The lump sum compensation should be reserved for the permanently incapacitated who have arrived at their minimum disability.

DELAYS IN SETTLEMENT

While many cases are being short-circuited by being dealt with by a medical referee, prolonged delay in settlement occurs in others. As delay has a most harmful effect on the mentality of the claimant, cases should be dealt with expeditiously. This could be done by means of a court of independent and expert medical assessors. Many cases offer no difficulty from the purely medical point of view.

Report on Mental Hospitals

The annual report of the London County Council on mental hospitals and on mental deficiency states that while the population of the administrative county of London is decreasing as the result of migration to the outer ring of Greater London there is every indication that the number of mental patients for which the council is responsible will increase for some years. This is explained by the fact that the migrants are largely young persons, which produces an increase in the average age of the remaining population, and by the increasing longevity of the population generally. Hence there is an increasing proportion of persons suffering from decay of their mental powers. In January 1934 the council had to provide accommodations for 21,813 mental patients. Some important remarks are made in the report on occupational therapy. Not until a few years ago was there any organized attempt to encourage the patients to occupy themselves in the domestic work of the hospital, in farm work or in the workshops. Recognition of the value of such occupation has led to the appointment in each of the large mental hospitals of a woman occupations officer and of a male officer in one hospital. It has been found that this innovation is a valuable aid in the difficult task of awakening interest in self-centered or listless patients and may lead to a mental improvement of which there were no previous signs. The possibility of extending occupation therapy is therefore under consideration.

The Sterilization of Women

At the Section of Obstetrics and Gynecology of the Royal Society of Medicine, an important discussion took place on the sterilization of women, including the indications, technique and legal position.

INDICATIONS FOR STERILIZATION

Mr Victor Lack mentioned five classes of disease in which sterilization was justifiable. 1. Chronic progressive general diseases that ran a downhill course, such as chronic rheumatic endocarditis, chronic nephritis, diabetes and disseminated sclerosis. Here pregnancy was a risk to life, though in some instances it might be possible to allow the patient to have one or two children. 2. Chronic diseases with a theoretical possibility of recovery, such as tuberculosis and hyperthyroidism.

3 Mental diseases, including epilepsy Sterilization was justifiable in a patient who had had puerperal insanity without obvious cause, also in patients with a bad family history who habitually produced defective children 4 Repeated cesarean section and repeated severe toxemia 5 Hereditary diseases, such as hemophilia and acholuric jaundice

VOLUNTARY UTERINE STERILIZATION

Dr C P Blacker, secretary of the Eugenic Society, said that 45 per cent of the children of mental defectives were defective or retarded He advocated voluntary sterilization, as the disadvantages of compulsory sterilization outweighed the advantages In Germany, unforeseen complications had arisen from the latter

The legal position was presented by a lawyer Mr Cecil Binney Any operation performed in the interests of the patient's health or life was permissible, but apart from this sterilization might be regarded as an offense and a person's consent was no defense against the charge of maiming With regard to lunatics and mental defectives the sterilization of persons who could not give consent and did not properly understand what was being proposed would be a still greater crime Sterilization for reasons of health was always lawful for eugenic reasons, probably unlawful in lunatics always unlawful unless for health reasons

TECHNIC OF STERILIZATION

Mr V B Green-Armstrong demonstrated on the screen what he considered to be the best method of temporary sterilization He mobilized the terminal inch of the fallopian tubes and with fine catgut buried the tube in a slit in the broad ligament The technic was simple and bloodless but care had to be taken that the vascular supply of the end of the tube was not disturbed and that no tension existed The advantage of the method was that in the event of remarriage or altered conditions the buried end could be freed again In many instances this was followed by pregnancy For permanent sterilization he demonstrated a method that he devised many years ago, of much use to the eugenicist as it involved only a few days in bed and no risk or pain He opened the uterovesical pouch through the vagina, retracted the bladder and brought the uterus down He then excised the cornual end of each tube sewed the cut edges, and closed the vaginal incision

Mr Aleck Bourne brought forward a simple technic which he had recently developed He cauterized the uterine openings of the tubes with a diathermy electrode, which was curved so as to follow the lateral wall of the uterus After some initial failures he could now get both tubes occluded as shown by the use of iodized oil The operation was quick and safe and could be done under gas in two minutes

Library of Orthopedic Surgery

In Liverpool, Hugh Owen Thomas laid a large part of the foundation of modern orthopedic surgery and his nephew and pupil Robert Jones followed him The Liverpool Medical Institution has decided to commemorate their work by forming a Hugh Owen Thomas and Robert Jones Library of Orthopedic Surgery, in which it is hoped that every phase of this subject will be represented An appeal has been made for contributions of books and articles on the subject These will form a nucleus of what it is hoped will become a complete orthopedic library in which the student, the postgraduate, the practitioner and the surgeon may learn all that is being done in this branch

Refugees from the German Persecution

Lord Rutherford who presides over the Academic Assistance Council formed for the help of Jewish and other scientists and scholars driven from Germany by the Nazi persecution, has

reviewed in the *Times* a pamphlet entitled "A Crisis in the University World," published by the council It is an impressive record of the work done in the last two years Of 650 scientists and scholars who have left Germany, 248 have already been reestablished in permanent positions Facilities for continuing their studies or research in universities and other institutions have been provided for 336 of the remainder Thus almost all have been retained within the university sphere, a magnificent demonstration of support for the principle of the preservation of learning In only a few instances could universities use their funds for this purpose Almost all the money has been raised by funds established by emergency academic committees in Europe and the United States A gratifying aspect of the work is that substantial support has been received both from Jewish and from non-Jewish sources In particular university teachers and graduates have given generously Lord Rutherford points out that the problem is neither in fact nor in implication a Jewish one alone and that it involves a principle demanding the support of all who believe in the freedom and security of learning The difficult problem still remains to transfer the 366 temporarily placed scholars into more permanent positions Many of them are engaged in subjects such as philosophy or the classics in which the field of absorption is more limited than in the natural sciences A majority of them are younger men and women without the international reputation that made it easier to assist their senior colleagues Yet it is the younger group because of its potentialities for future research that most deserves reestablishment The financial requirements of this work are small in proportion to its importance One man of vision and generosity could end this crisis in university history

March 1, 1935

Deficit in Social Insurance Budget

In an article by Dr G Fischer in the Dec 23 1934, *Concours medical* one sees that all is not gold that glitters in the social insurance question in France Although in force scarcely four years there have already been a large number of changes in the original law and many more are in prospect As the author of the article states, there are many squeaks to be heard in the machine indicating that the plan is not as easy to carry out as seemed to be the case when its authors with the best of motives in view, first proposed the plan, shortly after the World War Aside from the complaints on the part of the medical profession there is much discontent among the beneficiaries on account of the complicated "paper work" as it used to be termed in the U S Army, or "paperasserie," as the French call the many blanks to be filled out by the bureaucrats In addition, there is a multiplicity of procedure and loss of time incidental to the proper functioning of such an organization in a population of more than forty million people

From the beginning of the operation of the law in the fall of 1930 to the end of 1933 the total receipts paid by all those who were assured against illness maternity old age and death were about \$840,000,000 The government was obliged to add \$205,000,000 making a total of over a billion dollars

On the disbursement side \$185,000,000 was paid out by the agencies (Cassess de repartition) to those who were injured or ill, or to maternity cases Another distribution agency (Caisse de garantie) paid \$94,000,000 to those (above the age of 60) who were entitled to old age pensions Finally, the costs of administration amounted to \$45,000,000

The total payments thus (to the end of 1933) amounted to \$330,000,000 This does not include \$630,000,000 placed in the Central Deposit Office as a reserve fund

Of the \$45,000,000 listed as expenses of management, the central bureaus in charge took 59.40 per cent, while the agencies which have the responsibility of carrying out the law received only 40.6 per cent. According to Dr. Fischer, this indicates a faulty organization, and as a result all the agencies that come in contact with the assured find their funds in a deplorable state of deficit. In order to carry on their work, some of these primary centers of distribution have been obliged to borrow from the central depositories at a 4.5 per cent rate of interest in order to meet the claims of the assured who are directly under their supervision. When the law was first studied, the management costs were arbitrarily placed at 35 per cent. A survey made by the International Bureau of Labor showed even at that time (1928) that one must estimate the cost of administration to be 8 per cent of the receipts for the first five years, followed by a gradual decrease to 5 per cent. In Germany these charges vary between 7.58 and 11 per cent. In Rumania and Austria they are 7 per cent; in Sweden 9 per cent; in Switzerland 8.45 per cent; in Denmark 11 per cent and in Italy 20 per cent.

After all deductions are made in France, only a sum equal to between 40 and 50 per cent of the original amount paid in by the worker and his employer remain for settlement of claims. This amount ought to be between 80 and 85 per cent, a figure that exists in Germany, Czechoslovakia and Poland and still permits placing some of the funds in the reserves. Hence when one considers that only a sum equal to about 45 per cent of the total collected is available for distribution, it means that payment for maternity cases is quite inadequate, and for those who are obliged to be operated on the amount allowed is ridiculous.

The question that now presents itself in France is: How can such a state of affairs be improved? In order to meet the costs of management, the minister of labor stated before the French house of representatives that first, it will be necessary to fix the cost of administration at 7.5 per cent of the amount collected as premiums. Secondly, there have been organized in France recently a large number of private companies, termed "mutualités." Although their operations are under the supervision of the government, they fulfill all the objectives of state social insurance in insuring against illness, injury, maternity costs and old age. Instead of equal contributions, as in state insurance, by the employer and the employee, only the latter pays a premium. The scheme is purely voluntary and has grown so rapidly in importance that it has become a menace to the social insurance law of the government.

Eight million, or 65 per cent of those now eligible to insurance under the French social insurance law are now paying additional premiums voluntarily to these "mutualités." Recently an additional competitor, in the form of "benevolent associations" has appeared on the field, which will again add to the number of those who want voluntary insurance as a supplementary source of indemnity, aside from their obligatory state insurance. One of the congressmen, Mr. Dormian is of the opinion that the rapid increase in the number of adherents to these voluntary insurance societies shows that vast economies could be made in the management of the government insurance so that larger sums could be paid to those who are obligatorily insured.

Another critic of the social (state) insurance law maintains that one of the chief complaints is that it is too bureaucratic and that an effort should be made to have a more flexible, more rational and more live organization. He has even proposed that the management of the state insurance plan shall be placed in the hands of the private organizations such as the "mutualités" represent.

A defect in the French law is that payments for sickness cease at the end of six months, hence only those who suffer from ailments of relatively short duration can be cared for

That is, it covers only cases in which there are many loopholes for fraud to occur. How about syphilis, cancer, tuberculosis and similar chronic diseases, which need care for years? The result is that nearly two thirds of those who claim sickness indemnity are left uncared for. This includes 80,000 cases of tuberculosis and 5,000 cases of cancer, without counting cases of syphilis. Such an interval of six months during which indemnities are paid for illness ought to be modified. The minister of labor, whose department takes care of social insurance proposed on Nov. 29, 1934, certain changes in the law, which include allowances for women from the beginning of a pregnancy, also that the wives and children of those called for military service should receive support in the form of allowances, and, finally, a simpler method of making payments for premiums. At present one buys special stamps. Under the new proposals these premiums could be paid by the employer in the form of checks. Also the classification should be abandoned of those who must be insured in order to avoid cases in which a worker has not paid his full dues and thus loses his right to any indemnity.

Prof. Henri Hartmann Honored

Prof. Henri Hartmann of Paris has just been elected vice president of the Academy of Medicine. This is one of the highest honors that can be bestowed on a member.

Professor Hartmann has been a guest of the American Surgical Association and his work is familiar to all surgeons who visit Paris. Although past the age of 70, he is still active as the director of the large cancer service at one of the largest hospitals here.

Suppression of Advertising in Radio Programs

The majority of radio stations in France are owned by the government and every owner of a wireless set is obliged to pay an annual fee, varying in amount according to the size of the set. There have been so many protests by these taxpayers against paying the state to be told which soap is the best or which alcoholic appetizer created the healthiest appetite that the Department of Posts and Telegraphs has ordered all advertising and paid publicity to be suppressed in the programs broadcast by the stations controlled by the government. The chief complaints were that such publicity was sandwiched in between songs or at the end of concerts, which form the chief portion of French radio programs. There may be times when American listeners would covet a holiday in France to get out of earshot of commercial announcements.

Origin of the Follicle Stimulating Factor in the Urine of Pregnancy

Two interesting cases have been reported in the October 1934 issue of *Gynecologie et obstetrique* by Reeb, Nerson and Klem of Strasbourg. During the last few years, the diagnosis of the presence of a hydatidiform mole has been diagnosed by the presence in the urine during pregnancy of a marked increase (from ten to 100 times more than during a normal pregnancy) of the follicle stimulating factor; hence it is necessary only to inject a quantity of urine from ten to fifty times less into rabbits than in the case of a normal pregnancy. Recently cases have been reported, which are quoted, in which the amount of the follicle stimulating factor in the urine in cases of hydatidiform mole was not above the normal amount or was entirely absent.

This brings up the question as to whether this hormone has its origin during pregnancy in the hypophysis or is a product of the activity of the placenta. In the first case reported by Reeb, Nerson and Klem, the patient was a primipara, aged 26, seen in the fourth month of pregnancy. The presence of a

hydridiform mole was suspected. A total of 15 cc of urine was injected at intervals during three days into a young rabbit weighing 1,600 Gm. The rabbit was killed seventy hours after the first injection. There was a marked positive reaction in both ovaries. On the strength of this result and a negative roentgenogram a diagnosis of hydridiform mole was made and the uterus evacuated. A fetus 14 cm in length with hydranmios and an apparently normal placenta was found. The microscopic study, however, of the placental villi revealed a picture like that seen in a true hydridiform mole with the exception that there was an absence of vessels in the villi and of vesicular cells.

In the second case a multipara, aged 41, was seen during the fifth month of pregnancy because of frequent hemorrhages. A hydridiform mole being suspected, 0.6 cc of the urine was injected at intervals during three days into a young rabbit weighing 1,800 Gm. The rabbit was killed sixty-four hours after the first injection and showed a marked positive reaction in both ovaries. On account of this result and a negative roentgenogram a vaginal hysterotomy was performed and a dead fetus 16 cm long delivered. Aside from discrete hemorrhages in the placenta the latter appeared normal macroscopically. However, the microscopic examination revealed as in the first case, a marked proliferation of the cells covering the villi, with many mitoses. The interruption of pregnancy in both cases was justified by the hemorrhages, the negative roentgenogram and the markedly positive Aschheim-Zondek test indicative of hydridiform mole. In both cases the villi showed the active cellular proliferation seen in hydridiform mole, and for this reason the authors believe that these placental changes in the presence of ordinary pregnancies and in the absence of a hydridiform mole are responsible for the marked increase in the follicle stimulating factor in the urine.

Surgical Treatment of Gastric and Duodenal Ulcers

At the Oct. 28, 1934, meeting of the Royal Society of Medicine of Ghent, Finsterer of Vienna stated that subtotal resection of the stomach is the operation of choice in gastric and duodenal ulcer. In 363 such cases there were thirteen deaths, a mortality of 3.5 per cent.

In 920 operations for duodenal ulcer there were thirty-two deaths, a mortality of 3.4 per cent. These favorable results are in part due to the use of splanchnic anesthesia and to the method of anastomosis (Hofmeister-Finsterer technic). In 95.8 per cent of the cases of gastric ulcer, complete cure followed resection. The same was true of 94.6 per cent of the duodenal ulcer cases. Diarrhea following subtotal resection has been observed in only six cases and even here the diarrhea was of short duration. Finsterer has never seen a postoperative secondary or pernicious anemia. In cases of gastric or duodenal ulcer perforation, the intervention consists merely in closure of the perforation by suture.

In 273 resections for gastric ulcer, microscopic examination revealed the presence of cancer in sixty-three or 23.1 per cent. The prognosis in these cases is unfavorable. Eleven of twenty-six cases of this kind had a fatal outcome within five years. Jejunal ulcers following gastro-enterostomy should always be operated on radically. The operation should include removal of the anastomotic area ulcer-bearing area of the duodenum and two thirds or even three fourths of the stomach. Of 168 such operations for jejunal ulcer the outcome was fatal in nineteen, a mortality of 11.3 per cent. Operation should not be delayed in cases of gastrojejunal fistula lest the patient die of starvation. One should operate only if there are strict indications. If one has decided, however, to operate, only radical measures should be considered.

Automobile Accidents in Paris

Visitors to France will not be astonished to learn of the large number of deaths and more or less serious injuries which the chief of police of Paris has included in his annual report for 1934. In a city like Paris, where motorcycle police and speed laws are practically unknown, one is not surprised to find that for the year ended July 1, 1934, 28,000 persons were either killed or more or less severely injured, 9,000 of these accidents were to people crossing the streets, 10,000 to occupants of automobiles and 800 to policemen. A laudable effort has been made to mark crossings for pedestrians, which ought to be respected by automobilists, but a number of accidents were the result of persons being injured while traversing these crossings.

Experimental Sarcoma Following Injection of Thorium Dioxide

Professor Roussy, director of the new Cancer Institute, and his associates Oberling and Guérin reported some experimental work on sarcoma at the Dec. 18, 1934, meeting of the Academy of Medicine. One cc of a solution composed of equal parts of thorium dioxide sol and physiologic solution of sodium chloride was injected every three or four days either into the peritoneal cavity (series A) or into the subcutaneous tissue (series B) of the abdominal wall of fifty white mice. Five such injections were given in the interval from June 27 to July 11, 1933. Thirty-five animals dying of various intercurrent conditions during the first ten months are not included in either series. The other fifteen died between the tenth and the seventeenth month after the injections. Eight of these fifteen presented either peritoneal or subcutaneous sarcoma.

In the first series four out of ten mice in which thorium dioxide sol had been injected into the peritoneal cavity presented sarcomas that were typical on microscopic examination. In addition to an ascites there was a tumor mass, as large as a walnut at times free, at others pedunculated or forming a compact mass with adjacent viscera. In addition to a principal tumor there were smaller masses on the surface of the intestine, omentum or mesentery. The microscopic picture was that of a fibrosarcoma with numerous mitoses indicative of marked cellular activity, with evidence of invasion of the liver, pancreas, stomach, abdominal wall and diaphragm. The smaller nodules were apparently primary and not metastases. These sarcomas are found where the solution is most apt to accumulate in the upper and lower abdominal regions.

In the second series the solution had been injected into the subcutaneous tissue of the abdominal wall. Four of the five mice thus injected presented typical sarcomas the size of a prune within three or four months after the injections were begun. The sarcomas invaded the entire thickness of the abdominal wall and may ulcerate to such an extent that a perforation results, with hernial protrusion of the small intestine. On microscopic examination these abdominal wall experimental sarcomas show the structure of fibrosarcoma with cellular polymorphism and numerous mitoses. No visceral or lymph node metastases were ever observed. A transplantation of the sarcomas of the second series was attempted and was successful in five of fifty mice, killing four of the five mice in from three to four months. The results of a second transplantation from these four mice is still being studied.

The malignancy of these experimentally produced sarcomas is shown not only by their histologic characters but by the ability to transplant them. The only difficult point is to explain the absence of metastases, but this is often lacking in some forms of malignant neoplasms. The authors believe that these observations will prove important because they demonstrate that the use of other substances than the coal tar derivatives can result in the experimental production of malignant growths.

Reorganization of the University Instructors

Soon after the beginning of the new regime in Germany, it was announced that far-reaching changes in the personnel and the mode of instruction at the universities would be made. First came a law concerning the 'emeritization' and transference of university teachers. Previously the appointment of university instructors was subject to the laws of the various *lander*, but now the reich has taken over the right. The age for retirement has been placed uniformly at 65 whereas formerly in Prussia it was 68 while in Bavaria there was no limit. The internist Prof. Friedrich von Müller performed until recently the duties of his professorship and his clinic although considerably past 70. The professors are not however pensioned but 'emeritized,' which signifies that they continue to receive their salary undiminished (but none of the tuition money paid by students), whereas under the pension system they had received a pension that was much less than their salary. However, if the interests of the university demand it, 'emeritization' in a given case may be postponed by way of exception.

The second important change brought about by the law was to abolish the ruling that fully established university instructors could not be transferred to another institution against their will. Now, at least during the operation of this law from Dec 13, 1934 to Dec 31, 1937 they may be transferred without their consent to a similar chair in another German university. A professor, instead of being transferred, may be 'emeritized' if the reorganization makes it seem desirable to eliminate a chair or to combine one chair with another. It is planned to allow the various universities gradually to specialize in certain fields; for example, protestant theology might be particularly developed in Marburg, and mathematics and the natural sciences in Göttingen.

Furthermore, suitable rectors, or presidents for the administration of universities in the spirit of national socialism may be appointed. One of the first aims is to confirm the Führer principle in the universities, in which the rector becomes, as it were, the confidential adviser of the minister.

Further significant changes concern the mode of appointing university instructors, through which as is openly stated, a profound influence will be exerted over the intellectual life and the organization of the whole university system. Until recently the new appointees were, as a rule, selected from lists proposed by the faculties. These lists played an important part, being always much discussed and if the ministry appointed any one whose name was not on the list, it frequently awakened a storm of indignation in the faculty concerned. Now a change has come about, so that in all appointments the university commission of the national-socialist party has a voice, advising the ministries in their selection of candidates and exerting a controlling influence in the final choice. This has been emphatically stressed by the head of this commission, Professor Wirz, dermatologist, of Munich. In a short time thirty-four appointments have been made on the basis of this method. In some German *länder* the distinction between 'ordinary' and 'extraordinary' professors has been abolished. The main problem now is to apply principles of selection to the university instructors. A reform of the methods of appointment will not, however, suffice.

In keeping with this attitude is the new plan of habilitation (valid for the whole reich), which means provision for the testing and approval of the oncoming generation of instructors. A sharp distinction will henceforth be made between habilitation and *dozentur* or the acquisition of the right to teach in a

German university. The "privatdozent," who gave to the German university a peculiar cast, has dropped out. In place of the privatdozent there are now two titles: a new academic degree, 'Dr. habil,' for which every person with a doctor's title conferred by a university faculty is eligible but which does not grant the right to teach. This title is conferred as a purely academic procedure without reference to the need of new instructors. For the acquisition of this advanced doctor's degree a habilitation paper of scientific value and a scientific discussion before the faculty are required. The rector is invited to be present. If the rector and the faculty are convinced that 'the applicant is able to discuss questions pertaining to his specialty in a satisfactory manner,' the committee on instruction, if it agrees, authorizes the faculty to grant the request for habilitation. Thereupon the applicant receives the aforementioned title of Dr. habil. In addition to scientific requisites, a questionnaire as to the Aryan origin of the applicant and his wife are demanded.

The second chapter, which concerns the *dozentur*, or the actual acquisition of the *venia legendi*, presents some entirely new aspects. The same general qualifications hold for a dozent, or instructor, as for a public official. The minister of public instruction refers the applicants, who of course must hold the degree of Dr. habil., to a suitable faculty. The candidate must first submit to a public three-day teaching test the subjects for which the faculty must choose from three subjects proposed by the applicant. The rector and the representatives of the instructors and the students are present during the test. The rector sends a report on the test to the department of public instruction. Then the applicant reports for service in the work camp and to the Dozentenakademie, or academy of instructors (THE JOURNAL, Dec 16, 1933, p. 1980). A report on this work service is likewise sent to the department of public instruction. That department, with the cooperation of the federal minister of science, decides on the granting of the *venia legendi*. The question as to whether there is a need of university instructors plays a decisive part in the decision. The *venia legendi*, as granted, applies to all the universities of the German reich, whereas formerly it applied only to the university at which the test was held. However, removal to another university can be effected only with the consent of the minister, but a removal may be ordered by the minister without the consent of the candidate. The minister may also withdraw or restrict the *venia legendi*, if it seems desirable in the interest of the university. Those who had previously passed their habilitation test are immediately recognized as "dozenten," or instructors, and have the title of Dr. habil. This title is applicable also to those who no longer are teaching at a German university, provided they have previously been habilitated.

It is interesting to note what the university commission of the national-socialist party, which will exert an important influence on further developments, has said about university instructors. Professor Reiter, president of the federal board of health has emphasized that it is the duty of the physician of the Third Reich to provide not only for the care of the public health but also for the training of the German people in a type of 'thinking, feeling and doing' which will bring credit to the race from which they are sprung. The primary precondition is a biologically directed selection of university instructors and students. The decisive factors concern not only the intellectual performance but also the aptitudes, the adjustments and the world views. Any possible reactionary tendencies will be overcome. At present there is not sufficient good material to draw from in the filling of vacancies in the universities. It will require from five to six years of special training before an ideal university instructor will be available. Not until then shall we have the type of physician that is needed.

The Reform of Medical Instruction

The next goal is the reform of the course in medicine. It is expected that the necessary reforms can be introduced in the fall of 1935. It is, says Professor Wirz, the task of national socialism to create a new type of physician and a new medical profession. The old Virchow ideal of physician who considers the healing of the individual his sole task is today outmoded. The individual person stands no longer in the foreground but rather the people and the race in its entirety. The new training at the university must produce this type of physician. When the final provisions of the reforms have been announced, they will be described in detail.

The Official German Medical Report of the World War

The official German sanitary report of the World War 1914-1918, as prepared by the Heeres-Sanitäts Inspektion des Reichswehrministeriums has begun to be published. Volume III, which has just appeared, gives a survey of the number of persons killed, wounded and the victims of disease among the participants in the war. The number of medically treated wounds and illnesses amounts to more than 27,000,000. The details of the survey are based on the utilization of the huge mass of statistics contained in the official lists of the dead, and in the medical reports of the troops and the hospitals of the army in the field and the army of occupation. From September 1918 on, however, the reports are incomplete because of the revolutionary disturbances.

The total number of war participants in the army (exclusive of the marine and the protective forces in the colonies), up to the end of July 1918 was 13,100,000, or, if the 1900 levy, which had been called to the colors, is included, 13,300,000. During the four years of the war the average number of effectives in the army in the field and in the army of occupation was 6,372,000. Up to Dec. 31, 1933 (that is, including delayed reports), the total number of persons killed in action and dying from all causes is placed at 2,036,897. Of this number, 1,900,876 were killed or died during the war or during the border struggles in the east, 34,836 in the navy, and 1,185 in the colonies. In addition, 100,000 were reported missing, being presumably dead. The loss of human life is increased in one sense by the resulting diminution of births which for the present territory of the Reich is placed at 3,000,000 and at 3,500,000 for the prewar territory.

The number of persons totally blind as the result of war injuries was 2,734. The army in the field had 4,814,557 wounded men during the four years of the war.

Warning Against the Use of Dinitrophenol

On the basis of observations in other countries—particularly the United States—the federal bureau of health has called urgent attention to the dangers that may be associated with the use of dinitrophenol by persons unfamiliar with its properties. Dinitrophenol and preparations containing this substance, if used at all, should be used experimentally and only under constant observation in clinics and hospitals, especial care being taken to determine the therapeutic dosage on the basis of the body weight. The federal bureau of health will, if necessary, adopt requisite measures for the prevention of damage to the health of the population. Thus far, according to the best information obtainable, dinitrophenol is little used in Germany.

Coronary Infarcts

For years it has been known that coronary occlusion produces typical changes in the electrocardiogram. Professor Büchner and Dr. Haager studied fifty cases with the aid of Professor Weber of Bad Nauheim. The coronary arteries are connected with one another by such numerous anastomoses that only a sudden and total blocking can lead to an infarct. The blood flow through the coronary arteries according to

the research of Professor Rein, is entirely dependent on the heart performance and is controlled by the vagus. The infarct arises usually when an arteriosclerotic coronary vessel becomes thrombosed, which commonly takes place at night when the circulation has become retarded. The preferred site is the anterior branch, whereby the anterior wall of the heart, the apex and the ventral portion of the septum become infarcted. The second preferred site is the right coronary artery and leads to the infarction of the right ventricle and the posterior wall of the left ventricle. The infarction often penetrates the whole heart. Sometimes a rupture may occur. Disseminated fibrous areas are the residues of an old coronary insufficiency. If for the coronaries there is a discrepancy between heart performance and blood supply, an acute coronary insufficiency develops which clinically often takes the form of angina pectoris. If death ensues, necropsy reveals in such a case multiple disseminated necroses over the heart. Often in aortic insufficiency the coronary circulation is damaged to such an extent by the back flow during diastole and by the low blood pressure that angina pectoris may develop.

Professor Weber spoke on the same subject. One may note in the electrocardiogram the following departures from normal: (1) lengthening of the first ventricular complex, (2) flattening, or even downward deflection of the T wave, and (3) the so-called coronary wave. The current emanating from the stimulated muscle is biphasic. If the current is led off separately from the base and the apex of the heart, the base will give an upward deflection and the apex a downward deflection. If the current is led off from the base and the apex at the same time, one gets an electrocardiogram in which the upward directed current of the base (wave S) is brought down by the initial action of the apex. In wave T the action of the base again predominates, since it begins earlier and continues longer than the action of the apex. The negative deflection of the space between waves S and T is caused by an impaired myocardium. Likewise in an attack of hypoglycemia this portion of the electrocardiographic curve becomes negative and the result is the same whether mechanical or chemical disturbances prevent the necessary amount of oxygen from reaching the myocardium. It is important that the various leads show different changes depending on the site of the infarct. For example infarcts of the posterior wall are characterized by changes in the third lead. The so-called coronary wave presents itself particularly in the presence of a recent infarct. In the first and second leads one observes infarct changes in the anterior wall; in the second and third leads one notes changes in the posterior wall—infarct changes located in the base. The negative interspace between the S and the T waves does not justify any definite conclusions as to thrombosis and infarct but is often due to the action of a coronary insufficiency. Recent coronary thrombosis causes a marked drop in the T wave. It is more difficult to interpret the negative ST space in the first ventricular complex, which must result from injuries of the myocardium of various kinds. Oxygen deficiency accentuates the manifestations in the electrocardiogram. The experimental production of various degrees of oxygen deficiency constitutes an important test of heart functioning.

A Clearing House for Scientific Congresses

In the scientific congresses of the past there has been a certain lack of continuity. For this reason a central body that aims to aid in the organization of all German medical congresses and if feasible, of international congresses, has been created. The headquarters of this central body will be in Berlin, in the Langenbeck-Virchow Haus, where the Deutsche Gesellschaft für Chirurgie and the Berliner Medizinische Gesellschaft are likewise located. Heretofore the personnel of

the committees in charge of the organization of a given congress and of all the arrangements changed with every session of the congress. The purpose of the new central body is to serve as a clearing house of information and thus to prevent the collective positive and negative experience of the organizers of congresses from being lost.

Feb. 2 1935

Regulations Concerning Narcotics and Industrial Poisons

In December 1934 the minister of public health issued new regulations governing the use of narcotics and of industrial poisons. The regulations replaced dated back to 1918. The new regulations cover poisonous substances used not only for therapeutic but also for industrial purposes and they designate particularly the substances used as narcotics. The new regulations are of especial interest to physicians since they must be taken into account in the writing of prescriptions. Under narcotics are listed crude opium, prepared opium, opium for smoking, medicinal opium and its derivatives: morphine, heroin (diacetylmorphine), paramorfan, genomorphine, dilaudid, dicodid, eucodal, acedicon, also coca leaves and derivatives: crude cocaine, ecgonine, cannabis thebaine and benzylmorphine. All preparations, esters or salts containing any of the enumerated narcotics are to be regarded as narcotics within the meaning of these regulations even though prepared synthetically, diluted or adulterated. Tropacocaine is no longer to be regarded as a narcotic. With regard to the poisons that are in use in the industries, the crafts, agricultural pursuits, forestry and in the homes, no new provisions were promulgated although attention was called to substances that contain poison and are injurious to health if not handled properly or taken internally. To this class belong ether, ammonia, lyes, plant protectors containing barium, benzene, chromic acid for batteries, creolin, phenol, compound solution of cresol, tobacco extract, and others. Narcotics may no longer be sent through the mail so that physicians' samples must now be delivered by messengers. Physicians, veterinarians and dentists who require narcotics in the practice of medicine must keep a record of their purchases and must state how the substances were used so that government inspectors who examine their books will understand at once to what uses the narcotics were put. The prescribing of narcotics is prohibited in the form of medicated tablets containing more than 30 per cent in powder form or more than 15 per cent in solution of any of the following substances: morphine, heroin, paramorfan, genomorphine, dilaudid, dicodid, acedicon, eucodal, cocaine, thebaine, benzylmorphine or ecgonine. Cocaine in pure substance may be prescribed only for physicians for use in medicine. In prescribing narcotics, the physician must record the following matters on the prescription blank: the kind of drug and the quantity; in the case of powders the amount of the single dose; the directions for taking; the name of the patient, and his own signature together with stamp. Prescriptions for cocaine and cannabis preparations may be used but once and may not be refilled. The law deals also with codeine (methyilmorphine) and ethylmorphine hydrochloride which are put in the same category as narcotics so far as their production, their importation and exportation and the wholesale trade are concerned. Physicians having their own pharmacy need observe only the ordinary restrictions in the dispensing of drugs belonging to this group.

New Treatment for Injured Joints

At one of the recent sessions of the Vienna Medical Society Dr. Kraus of the Surgical Clinic demonstrated a new method of treating the so frequent distortions of joints. In the past

two groups of distortions have been distinguished: the mild and the severe type. The former have usually been given little or no treatment. In the second group, fixation over a considerable period was employed, various kinds of bandages being used, particularly the plaster cast, which played an important part. Subsequent examinations in the many cases reaching the second emergency station of the Vienna General Hospital, and of 1,843 sport devotees who came to the sport consultation center of the second clinic, gave the surprising result that a restitutio ad integrum is not secured by any method. Particularly after the use of plaster casts, one finds frequently marked vulnerability of the joints, a tendency to recurrence, loose joints, swelling, and pain. Complete cures and a shortening of the period of recovery which is of so great social importance, were rare. It was observed repeatedly that untreated patients who applied the necessary energy to overcome the severe pain and made immediate use of the injured joints recovered most rapidly and with the best results. Likewise subsequent examinations of lacerated ligaments yielded similar results. It is well known among the working classes that cold applications effect a diminution of pain. Further researches in this direction have shown that cold anesthesia applied to the skin (ethyl chloride) produces a far reaching desensitization of the ligamentary apparatus of the joints and that active movements during the period of anesthesia will release a blocked joint painlessly and usually completely.

From this observation it is possible to deduce two important principles. Anesthesia of the sensitive area over a joint exerts an analgesic effect in lesions of the ligamentary apparatus and a single interruption of the pain and of the muscle block will usually restore the disturbed function. On the basis of these considerations and observations, therefore, the following procedure was devised. After roentgenologic verification of the diagnosis, the pain point of the injured joint is determined and ethyl chloride is applied. The period of freedom from pain is lengthened by application of a cold producing mixture (alcohol-ether-acetone-camphor). Then the patient is required to make active movements, which are continued for from ten to twenty minutes. Often a second and a third application of anesthesia is necessary. The patient is instructed to use at home compresses dipped in a 70 per cent alcohol solution and, at the same time, to hold the joint over steam. This may be repeated from three to six times during the day. In several cases two or three treatments after the method described are necessary in order to obtain a complete restoration of working capacity and ability to participate in sports. Thus far fifty cases have been treated by this method, namely, thirty-eight sprung joints, four medial lateral ligaments, six fingers and two distortions of the spinal column. In none of the cases was any injury of the skin observed but it is well to oil the skin in advance. Patients who limped badly previously could leave the ambulatorium walking normally in spite of the distortion. It must, however, be emphasized that not all cases can be treated in this manner. A considerable number of severe cases require a plaster cast, injections into the ligamentary apparatus or an operative intervention. But it is certain that the method described in many cases of this so important injury will bring a significant improvement in the therapy and a considerable shortening of the duration of the disorder.

Professor Finsterer Succeeds Professor Schnitzler

Professor Finsterer has been chosen to fill the vacancy in the surgical department of the second largest Vienna hospital. He has acquired a reputation by reason of his method for abdominal operations under local or spinal anesthesia, in fact, it is no exaggeration to speak of the Finsterer school in Vienna. He is 59 years old. His training was obtained in the Vienna clinics.

Marriages

LAMAR L LANCASTER, Bartow, Fla, to Miss Mildred Alberta Dunn of Bogalusa, La, at Tallahassee Fla, March 18

HUNTER L GREGORY, Stockton, Calif to Mrs Dorothy De Graff Weaver of San Francisco February 1

OSCAR McLAUGHLIN of Rocky Hill Ohio, to Mrs Carrie Davis Eisman of Gallipolis, January 20

BERNARD VIENER to Miss Rebecca Cohen, both of Harrisburg, Pa, at Philadelphia March 17

MURIEL ADFELINE CASE Wallingford, Conn, to Mr Arthur R Downer of Hamden March 16

ROBERT E HARPIS, Brooklyn, to Miss Dorothy Clair Hussie of New York February 9

ROBERT J SEMONS, Carey, Ohio, to Miss Dorothy Kemper of Cincinnati February 25

POWELL W JOYNER to Miss Dorothy Marion Dunn both of Enfield, N C March 9

HOWARD C MOLOY to Miss Elizabeth Ewart Metzger, both of New York, March 2

SALL A SCHWARTZ to Miss Helen Judith Skinder both of New York March 16

Deaths

Horace David Arnold, Boston, Harvard University Medical School, Boston, 1889 member of the House of Delegates of the American Medical Association 1908-1913, and member of the Council on Medical Education 1913-1923 member of the Massachusetts Medical Society and the American Clinical and Climatological Association past president of the Suffolk District Medical Society at one time instructor and professor of clinical medicine Tufts College Medical School dean of the Harvard University Medical School Courses for Graduates 1912-1916 and later director, during the World War was assigned to duty at the surgeon general's office in Washington later serving as supervisor of medical education of the army division, formerly member and president of the National Board of Medical Examiners, and member of the State Board of Registration in Medicine, at various times on the staffs of the Boston Dispensary and the Boston City Hospital aged 72 died March 11 at his home in Waltham

Julius John Valentine of New York Columbia University College of Physicians and Surgeons New York 1905 professor of urology, New York Polyclinic Medical School and Hospital, member of the Associated Anesthetists of the United States and Canada and the American Urological Association fellow of the American College of Surgeons served during the World War on the staff of the Morrisania City Hospital, was recently decorated by the government of Venezuela for services rendered to that country past president of the Pan American Medical Association aged 52 died March 11 in the New York Orthopedic Hospital of pneumonia, following an operation

George Hoyt Bigelow of Boston Harvard University Medical School, Boston, 1916, health commissioner of Massachusetts, 1925-1933 and director of the division of communicable diseases, state department of health, 1924-1925 served during the World War, past president of the American Society for the Control of Cancer since 1934 director of the Massachusetts General Hospital and the Massachusetts Eye and Ear Infirmary director of industrial medicine and hygiene Antioch College, Yellow Springs Ohio 1921-1922 and director of the Cornell Clinic New York 1922-1924 aged 44 was found dead, March 23 in a reservoir in Framingham

George A Carpenter of Fargo, N D, Minnesota Hospital College, Minneapolis 1885 formerly counselor of the first district and past president of the North Dakota State Medical Association fellow of the American College of Surgeons served during the World War, at one time county health officer for six years member of the school board member of insanity board county board of health on the advisory board of St John's Hospital member of the staff of the Florence Crittenton Home aged 72 died February 23 as the result of chronic arthritis and heart disease

Harry Austin Sifton of Milwaukee University of Michigan Department of Medicine and Surgery, Ann Arbor, 1886 fellow of the American College of Surgeons formerly pro-

fessor of clinical surgery Wisconsin College of Physicians and Surgeons, chief of staff of Milwaukee Hospital for sixteen years consulting surgeon to Columbia Hospital and Johnston Emergency Hospital aged 67, died, February 27 in Phoenix, Ariz, of coronary sclerosis

Arthur Alfred Pratte of Keene, N H, School of Medicine and Surgery of Montreal, Que Canada 1893 member of the New England Otological and Laryngological Society, past president and secretary of the Cheshire County Medical Society, chairman of the city board of health formerly school physician and city health officer, on the staff of the Elliot Community Hospital aged 65, died February 4 of coronary thrombosis

James Monroe Witt, Waco Texas Tulane University of Louisiana Medical Department New Orleans, 1885, member of the State Medical Association of Texas, past president of the McLennan County Medical Society member of the state board of medical examiners on the staffs of the Central Texas Baptist Sanitarium and the Providence Sanitarium, aged 84, died February 22, of bronchopneumonia and bilateral pyelonephritis

Ira Groff Shoemaker of Reading Pa Medico-Chirurgical College of Philadelphia, 1891, past president of the Medical Society of the State of Pennsylvania and formerly councilor of the third district past president and secretary of the Berks County Medical Society at one time member of the school board aged 65 for many years on the staff of the Reading Hospital where he died, February 28 of ruptured duodenal ulcer

William Hamilton Miller Little Rock Ark. Arkansas Industrial University Medical Department Little Rock 1888, Bellevue Hospital Medical College New York 1889, member of the Arkansas Medical Society emeritus professor of obstetrics University of Arkansas School of Medicine member of the staffs of the Baptist State Hospital and St Vincent's Infirmary aged 67 died, January 23 of coronary thrombosis

Louis Joseph Cassano, New York Fordham University School of Medicine New York 1921 member of the Medical Society of the State of New York aged 37 on the staffs of the Columbus and Fordham hospitals New York, and St Joseph's Hospital Yonkers where he died March 1 of acute mastoiditis cavernous sinus thrombosis and meningitis

David Michael Roberts of Major M C U S Army, Fort Bragg N C Medical College of Ohio Cincinnati, 1895 served in the Federal Service as a contract surgeon from 1898 to 1903 served during the World War entered the medical corps of the U S Army as a major in 1920 aged 62, died February 27 in Kona Hawaii of coronary disease

Oscar Mitchell Unger, Pawtucket R I, University of Michigan Medical School Ann Arbor 1915 member of the Rhode Island Medical Society member of the New England Roentgen Ray Society on the staff of the Notre Dame Hospital Central Falls aged 44 died suddenly February 20, in the Memorial Hospital of cerebral hemorrhage

John G W Westerhoff of Carleton Neb Medical Department of Omaha University 1899 past president of the Thayer County Medical Society served during the World War formerly member of the state legislature and board of education aged 64 died February 23 in St Elizabeth's Hospital Lincoln of heart disease and diabetes mellitus

Leslie Alonzo Purifoy of El Dorado Ark Rush Medical College Chicago 1930 past president and secretary of the Union County Medical Society on the staffs of the Henry C. Rosamond Memorial Hospital and the Warner Brown Hospital, aged 30 died February 1 of coronary embolus as the result of injuries received in an automobile accident.

Melvin Samuel Rosenthal of Baltimore College of Physicians and Surgeons, Baltimore 1891 professor of dermatology, University of Maryland School of Medicine fellow of the American College of Surgeons aged 65 on the staffs of the Mercy Hospital and the Sinai Hospital where he died February 16 of carcinoma of the rectum

Jane W M Skolfield, Salt Lake City Denver and Gross College of Medicine Denver 1907 member of the Utah State Medical Association vice president of the board of directors of the Utah State Industrial School Ogden on the staff of the Latter Day Saints Children's Hospital aged 68, died, February 11, of chronic myocarditis

Robert Alexander Walker of Menominee, Mich University of Bishop College Faculty of Medicine, Montreal Que, Canada 1895 past president of the Menominee County Medical Society fellow of the American College of Surgeons on the staff of St Joseph's Hospital aged 63, was found dead March 1 of cerebral hemorrhage

James Joseph Norton Westfield Mass. New York University, University and Bellevue Hospital Medical College, 1908 member of the Massachusetts Medical Society and the New England Obstetrical and Gynecological Society on the staff of the Noble Hospital aged 50, died January 19 in St Francis Hospital, Hartford Conn. of epithelioma with metastasis to the liver

Joseph Wheeler Smith Jr ♂ Major U S Army, retired Eugene, Ore. Long Island College Hospital Brooklyn 1913 served during the World War was appointed a first lieutenant in the medical corps of the U S Army in 1918 and in 1920 was made a captain and in 1929 a major was retired in 1934 aged 44, died, January 28

Murray A Russell Washington D C Georgetown University School of Medicine, Washington 1906 at one time associate clinical professor of surgery at his alma mater fellow of the American College of Surgeons formerly consulting surgeon to St Elizabeths Hospital (Psychiatric Department) aged 53, died, February 19

Lewis Clinton Day ♂ Elmira N Y University of Vermont College of Medicine Burlington 1904 formerly physician in the Indian Service health officer of the town of Elmira for many years on the staff of the State Reformatory aged 57, died March 1, in St Josephs Hospital of carcinoma of the stomach

Frederick McNaughton Robertson, Bristol, N H Harvard University Medical School Boston, 1901 member of the New Hampshire Medical Society served during the World War on the staffs of the Margaret Pillsbury Hospital, Concord and the Franklin (N H) Hospital aged 58 died January 26

Ernest Lackner, Chicago Bennett College of Eclectic Medicine and Surgery Chicago 1872 past president of the Southside branch of the Chicago Medical Society for many years on the staffs of the Michael Reese and Grant hospitals, aged 83, died, March 14 of carcinoma of the gallbladder

George Harvey Guth, Staten Island N Y University of Pennsylvania Department of Medicine Philadelphia 1903 served during the World War acting assistant surgeon U S Public Health Service aged 64 died February 16 in the U S Marine Hospital of carcinoma of the intestine

John Clarence Kepler ♂ Kirkville Iowa Keokuk Medical College College of Physicians and Surgeons 1905 past president of the Wapello County Medical Society aged 57 on the staff of St Joseph Hospital Ottumwa where he died February 17, of cerebral hemorrhage

Charles Plummer Buzzell ♂ Cleveland N D University of Vermont College of Medicine, Burlington 1892 past president of the Stutsman County Medical Society aged 67 died February 15, in the Bismarck (N D) Hospital of cholecystitis, hepatitis and hemiplegia

Edward Simon Murphy ♂ Dixon Ill Rush Medical College, Chicago, 1897 fellow of the American College of Surgeons, past president of the Illinois Tuberculosis Association on the staff of Dixon Public Hospital, aged 64 died March 22, of cerebral hemorrhage

Cyril Herman Burger, Winnipeg Manit. Canada L.R.C.P. L.R.C.S., Edinburgh and L.F.P.S. Glasgow 1899 member of the Radiological Society of North America aged 66, died, February 27, in the Winnipeg General Hospital of carcinoma of the stomach

John Davis Dabney Ware ♂ Baltimore University of Virginia Department of Medicine, Charlottesville 1929 member of the Medical Society of Virginia resident physician to the Johns Hopkins Hospital, aged 31 died suddenly February 23 of heart disease

Otho H Williams Ragan, Hagerstown Md University of Maryland School of Medicine Baltimore 1874 fellow of the American College of Surgeons formerly on the staff of the Washington County Hospital, aged 81, died, January 15, of pneumonia

James Lundie Barton, Memphis Tenn Vanderbilt University School of Medicine Nashville 1895 member of the Tennessee State Medical Association, past president of the Memphis and Shelby County Medical Society aged 67, died January 6

Harry Seltzer Meily, Carlisle Pa Hahnemann Medical College and Hospital of Philadelphia 1898 member of the Medical Society of the State of Pennsylvania on the staff of the Carlisle Hospital aged 81 died February 24 of angina pectoris

Donald Raymund Smith, Eldridge Calif, Cooper Medical College, San Francisco, 1899 formerly superintendent of the Mendocino State Hospital, Talmage assistant superintendent of the Sonoma State Home aged 60, died suddenly, of heart disease

Claude Wellington Batdorf, Harrisburg, Pa, University of Pennsylvania School of Medicine Philadelphia 1911, member of the Medical Society of the State of Pennsylvania on the staff of the Harrisburg Polyclinic aged 47 died, January 21

Raphael Nassar Joseph, Middleboro, Mass., Georgetown University School of Medicine, Washington, D C, 1933, house physician to the Lakeville State Sanatorium, aged 26 died, March 2 of lobar pneumonia and pneumococcal meningitis

Stacy Barcroft Dimond ♂ Albany, Ill., State University of Iowa College of Medicine, Iowa City, 1889, also a druggist, aged 71 died, March 8 in the Jane Lamb Hospital Clinton Iowa of pulmonary embolus following an appendectomy

Benjamin Franklin Elfrink ♂ Chenoa, Ill., Rush Medical College Chicago, 1902 past president of the Livingston County Medical Society at one time mayor, formerly president of the school board, aged 60 died, March 12, of nephritis

Milton D Norris ♂ Eldersburg, Md., College of Physicians and Surgeons Baltimore, 1892, past president of the Carroll County Medical Society, veteran of the Spanish-American War aged 63 died February 17, of heart disease

Josephine Walter, New York Woman's Medical College of the New York Infirmary for Women and Children New York, 1882 member of the Medical Society of the State of New York aged 84 died February 26, of pneumonia

Otis Bush Mallow, Hines, Ill., Medical College of Ohio Cincinnati 1901 served during the World War chief of the diagnostic center Veterans Administration Facility, aged 59, died, March 10, of a self inflicted bullet wound

Harry Clifford Antle, Chickasha, Okla., University Medical College of Kansas City, 1904 member of the Oklahoma State Medical Association, served during the World War, aged 52, died February 7, of hepatic cirrhosis

George Clayton Zimmerman, Philadelphia Hahnemann Medical College and Hospital of Philadelphia, 1933 member of the staffs of St Luke's Hospital and the Children's Hospital aged 33, died, February 21, of lymphosarcoma

François de Borgia Bergeron, Fall River, Mass School of Medicine and Surgery of Montreal, Que., Canada, 1894, on the staff of St Anne's Hospital aged 64 died, February 27 of coronary thrombosis and arteriosclerosis

Charles Dudley Underhill, Staunton, Va., Harvard University Medical School, Boston, 1888 veteran of the Spanish-American War aged 68, died, January 5, in the King's Daughters Hospital, of bronchopneumonia

Lucy Appleton, Central Falls, R I, Boston University School of Medicine, 1887 formerly on the staff of the Massachusetts Memorial Hospitals, Boston, aged 86, died, February 23, of chronic myocarditis and endocarditis

Carl Kaiser Wagener ♂ Pittsburgh University of Pittsburgh School of Medicine, 1910, member of the American Academy of Pediatrics, served during the World War aged 51, died, February 26, of heart disease

John F Reilly, Rensselaer, N Y Albany (N Y) Medical College, 1883, formerly health officer of Rensselaer consulting obstetrician to St Peter's Hospital, Albany, aged 71, died, March 3, of coronary thrombosis

Benjamin Franklin Roe, ♂ Chetopa, Kan University Medical College of Kansas City, 1908 member of the Kansas Medical Society, president of the board of education, aged 63, died February 17, of angina pectoris

Frank Eugene Andrews, Adrian, Mich., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1878, member of the Michigan State Medical Society, formerly mayor, aged 77 died January 20

Adolph W Lakemeyer, Chicago Rush Medical College Chicago 1902, aged 62 for many years on the staff of the Norwegian-American Hospital where he died, March 12, of a self inflicted bullet wound

William Melvin Ramsay, Jonesboro, Tenn Vanderbilt University School of Medicine, Nashville, 1887 aged 75 died February 14, in a hospital at Greeneville, of senile gangrene and hypostatic pneumonia

Charles August Riemcke, Yakima Wash State University of Iowa College of Medicine Iowa City, 1909 member of the Washington State Medical Association, aged 52 died January 21

Philip Ross Watkins, Mena, Ark., Vanderbilt University School of Medicine, Nashville, Tenn., 1893, member of the Arkansas Medical Society, aged 69, died, February 24, of pneumonia.

Charles Adrian Julian ♂ Greensboro, N. C., Louisville (Ky.) Medical College, 1888, aged 68, on the staff of the Wesley Long Hospital, where he died, February 15, of pneumonia.

Edwin Lamar Nichols, Raleigh, N. C., Medical College of the State of South Carolina Charleston, 1934, aged 25, intern at the Rex Hospital where he died, March 4, of septicemia.

Thomas Ellis Tucker, Monroeville Ala. University of Alabama School of Medicine 1920 formerly health officer of Houston County aged 43, died Dec 19, 1934 in a hospital at Selma.

John Parker Dickson, Keokuk Iowa State University of Iowa College of Medicine Iowa City, 1888, also a pharmacist aged 73 died February 1, of hypertrophy of the prostate and uremia.

Powhatan Stanley Schenck, Norfolk Va., College of Physicians and Surgeons Baltimore, 1881 formerly director of public welfare and health commissioner aged 71 died January 24.

George Arnold Woodcock, Cottonwood, Idaho College of Physician and Surgeons of Chicago 1894 member of the Idaho State Medical Association aged 64 died Dec 20 1934.

H. S. Copeland, Dresden Tenn. University of Tennessee Medical Department, Nashville, 1893 formerly bank president aged 66, died January 28 in St. Thomas Hospital Nashville.

Amos Charles Fey ♂ Galesburg Ill. Northwestern University Medical School Chicago 1925 aged 34 on the staff of St. Mary's Hospital where he died March 3 of pneumonia.

Charles S. Means, Wilson, Pa. Jefferson Medical College of Philadelphia 1883, formerly on the staff of St. Agnes Hospital, Philadelphia, aged 72 died February 19 of uremia.

Edward Kenneth Wolff, Media Pa. Temple University School of Medicine, Philadelphia 1910 on the staff of the Media Hospital aged 50 died March 1 of heart disease.

James Archibald McNiven, Aberdeen Wash. University of Michigan Department of Medicine and Surgery Ann Arbor, 1891 aged 80 died, February 4, of cerebral hemorrhage.

Charles L. Allen, Cosby, Mo. Central Medical College of St. Joseph, 1898 member of the Missouri State Medical Association aged 61 died, Dec 8 1934 of arteriosclerosis.

Charles D. Napier, Blenheim, S. C. Medical College of South Carolina Charleston 1898 member of the South Carolina Medical Association aged 58, died January 7.

Alexander Vernon Webster, Vancouver B. C., Canada McGill University Faculty of Medicine Montreal Que. 1912 aged 50 died February 14 of coronary sclerosis.

William Crawford Mackintosh, San Francisco Cooper Medical College San Francisco 1910 fellow of the American College of Surgeons aged 50 died January 10.

Jay Frederick Pitts, Chicago National Medical University Chicago, 1904 aged 56 died February 12 in the Westlake Hospital, Melrose Park, Ill. of heart disease.

Lee W. Wheeler, Kite Ga. University of Georgia Medical Department Augusta 1900 aged 64 died January 14 in a hospital at Dublin, of valvular heart disease.

Lee J. Knerr, Philadelphia Hahnemann Medical College of Philadelphia, 1880, aged 77 died February 17, of gastric hemorrhage and carcinoma of the prostate.

Malcolm Storer ♂ Boston Harvard University Medical School, Boston, 1889 formerly instructor in gynecology at his alma mater aged 72, died, January 2.

Wilbert Shallenberger, Chicago Barnes Medical College St. Louis, 1901, Illinois Medical College Chicago 1902, aged 60, died, March 17, of carcinomatosis.

William Cornelius Pressly, Troy, Tenn., University of the City of New York Medical Department 1889 aged 77 died, February 18 of arteriosclerosis.

Karl Elmer Ochs ♂ Cleveland Western Reserve University Medical Department, Cleveland 1904 aged 54 died suddenly, February 5, of heart disease.

Christopher C. Banta, Coal Mo. University of Nashville (Tenn.) Medical Department, 1888, aged 68, died Dec 2 1934 of carcinoma of the sigmoid.

Daniel Webster Dorman, Boston College of Physicians and Surgeons, Boston 1893 aged 70, died, January 27, of myocarditis and arteriosclerosis.

Benjamin Anthony Robinson, Sayreville, N. J., University of the City of New York Medical Department, 1892, aged 72, died Dec 8, 1934.

Leonard Melvin Pulsifer, Davis, Calif., University of the City of New York Medical Department, 1888, aged 66 died, January 5, of heart disease.

Henry John Brewer, Brooklyn, Long Island College Hospital, Brooklyn, 1880 Civil War veteran, formerly coroner, aged 88, died, January 9.

William Hendricks, Chicago, Keokuk (Iowa) Medical College, 1891 aged 86, died March 14 of chronic myocarditis and acute nephritis.

James A. Humphrey, Martha Okla. Missouri Medical College, St. Louis 1890 aged 70, died February 17, of hypertension and myocarditis.

Erwin R. Wright, Philadelphia, Detroit Medical College 1885 aged 76 died February 2, in the Presbyterian Hospital of bronchopneumonia.

William Whupper Purnell, Berkeley Calif. Howard University College of Medicine, Washington D. C., 1893, aged 65 died January 2.

Thomas Hayne Wedaman, Johnston S. C., University of Maryland School of Medicine Baltimore 1909 aged 52 died, suddenly January 9.

Walter Keene Prichard ♂ Cloverdale Ind., Miami Medical College Cleveland, 1882 aged 75 died February 8 of phlegmonous erysipelas.

Emil Bernhardt Quade, Wausau Wis., Bennett College of Eclectic Medicine and Surgery, Chicago 1901, aged 57 died January 31.

Joseph Edward Duxbury, Central Falls, R. I. University of the City of New York Medical Department 1891 aged 67 died in January.

Edward Franklin Stevens, Seattle Medical School of Maine Portland 1887 aged 87 died February 12, of chronic myocarditis.

William G. Eaves, Bremond Texas (licensed in Texas under the Act of 1907) died Dec. 25 1934.

Tracy R. Clark, Clovis, Calif., Missouri Medical College St. Louis 1880 aged 80 died, January 28.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

BEER AND GLYCOSURIA

To the Editor—A few months ago I examined about thirty applicants for a job on some construction work. Several specimens of urine examined showed a reducing substance with Fehling's solution and two gave a typical reaction for sugar. Asked if they had been drinking beer, they answered in the affirmative. The weather was very hot and one man stated that he drank nine glasses of beer during the day or that afternoon before he was examined. What percentage of sugar is contained in beer and what type? Is an excess of beer liable to cause a reaction as above?

J. C. DRAKE, M.D., Kerman, Calif.

ANSWER—Carbohydrate as such is present in beer chiefly as maltose and dextrins. The dextrose equivalent of beer including the sugar derived from protein, glycerin, lactic acid and so on is about 12 Gm. to the 8 ounce glass. In addition to this, however, each glass of beer contains about 60 calories in the form of alcohol. Thus the 9 glasses of beer that one man drank would represent 108 Gm. of carbohydrate or 432 calories plus 540 calories from alcohol, a total of almost 1,000 extra calories for the day. Although alcohol does not go to form sugar, it spares sugar taken in the diet so that the available carbohydrate in that person might then be high enough to cause glycosuria.

TACHYCARDIA WITH INFECTION

To the Editor—A white girl aged 15, height 63 inches (160 cm), weight 127 pounds (57.6 kg.) seen in September, complained of general lassitude, easy fatigue, attacks of rapid heart beat associated with pain over the right parietal region and intermittent fever. The family and general past history is negative until the winter of 1932 when the patient first complained of weakness, fatigue and recurrent attacks of pain in the right lower quadrant. These symptoms recurred until in March 1933 a chronically inflamed appendix containing fecoliths was removed. On the third postoperative day a pulse of 140 was recorded without apparent cause. This subsided and convalescence was normal. The attacks of pain in the right lower quadrant have not reappeared but the paroxysmal attacks of tachycardia continue to reappear at intervals of four to six weeks. There is no apparent predisposing factor. Fever usually accompanies these attacks varying from 99 to 100.4 F. The patient feels weak and exhausted. The tachycardia usually subsides spontaneously, the pulse rate rarely going below 90 per minute, however. The elevation of temperature usually persists for several days. Dull pain in the right parietal region frequently but not always accompanies the tachycardia. The appetite is fair, digestion seems normal and the bowels act well as do the kidneys. The mentality is a little above the average. Menstruation is regular and of normal amounts and the menstrual cycle bears no relation to the attacks of tachycardia. The patient is well developed and well nourished. The throat is clean. There is slight cloudiness of the right maxillary sinus but there are no subjective signs. The chest and lungs are normal. The heart sounds are normal, the area of cardiac dullness is not increased and no murmurs are present. Abdominal examination is negative except for a well healed right rectus scar. The spleen is not palpable. The reflexes are normal. There is no edema of the extremities. The following laboratory work has been done: basal metabolic rate normal (plus 10), white blood count 8,900 (temperature normal) and 11,000 (temperature 99.5), polymorphonuclears 68 per cent, small lymphocytes 22 per cent, large lymphocytes 6 per cent, mononuclear cells 10 per cent, red blood cells 5,100,000 per cubic millimeter, hemoglobin 90 per cent, agglutination for Brucella abortus, lymphoid and paratyphus A and B all negative, tuberculin tests with 0.0002 mg. and 0.005 mg. both negative, catheterized specimen of urine negative both chemically and microscopically, fluoroscopy of heart and lungs negative. In view of these results would you kindly suggest further lines of attack in this case and possible diagnoses that may assist in helping this patient? Please omit name.

M.D. Ohio

ANSWER—The presence of fever and leukocytosis in the attacks described strongly suggests an infectious etiology. The initiation of the attacks following an appendectomy suggests the abdominal cavity as a source of the infection. An infection about the appendix may be carried upward behind the ascending colon and produce metastatic foci about the liver, gallbladder or subphrenic area. It may proceed behind the peritoneum to the region of the right kidney. The lymph channels along the mesenteric root may carry the infection upward to the right side of the abdomen, and the course may proceed upward behind the descending colon to the spleen and left portion of the liver. The bases of the lungs should be investigated for evidence of infection extending upward through the diaphragm.

Metastatic infection is not infrequently found in the pelvis.

This explanation would presuppose a low grade nonsuppurative adenitis from which, at intervals, a sufficient dose of toxin is discharged to produce the attacks described. The continued

presence of the infection would account well for the general lassitude and easy fatigue and continuously rapid pulse.

Such a low grade infection need not necessarily be located in the abdomen or pelvis. It would seem most probable in this case because of the condition of the appendix, but such an infection may occur about the hilar lymph glands or even in the sinuses of the skull.

The parietal headache suggests the latter possibility, although the headache might easily be explained as a toxic manifestation.

Paroxysmal tachycardia may be fairly well ruled out because of the occurrence of fever and leukocytosis. In addition, the rate is rather low for such an abnormal rhythm.

The treatment has not been detailed, but it would seem logical, if the case is considered an infection, to insist on a prolonged period of rest in bed. The program should be pursued until the attacks fail to appear at the usual time interval. This would mean at least six weeks and might have to be prolonged over a period of months.

PHYSICAL EFFICIENCY TESTS

To the Editor—I am interested in tests of physical efficiency but have not been able to find an examination that results in an adequate expression of an adult's actual physical state. The tests ordinarily used by educators—Roger's, Pignet's, Taylor's, Dreyer's, Martin's and Sargent's—all seem to be based on questionable empiricism or are actually fanciful. The cardiovascular performance and nonperformance tests are inconsistent when used in a large group of men or women. I should appreciate references and a statement of the accepted medical evaluation of such tests. Please omit name.

M.D. Maine

ANSWER—A dependable index of health and physical efficiency would be valuable, and numerous efforts have been made to develop tests for this purpose. Most of the tests proposed, some of which have been widely used and called physical efficiency tests, are based on the effects of changes in posture or a specified amount of exercise on the pulse rate, blood pressure and respiration. Actually, what these tests measure is only the reaction of the cardiovascular system to a given amount of effort at a particular time. Physical efficiency is dependent on much more than this. Although differences between the results of these tests can be demonstrated in selected groups of subjects, the variability of results produced in individual cases by unimportant and transitory factors, such as nervousness, excitement and fatigue, is so great as to make the tests of little value in individual diagnosis or in the estimation of individual physical efficiency. Critical analyses of certain of these tests are contained in the following:

Brittingham, W. H. and White, P. D. Cardiac Function Tests. *THE JOURNAL*, Dec. 2, 1922, p. 1901.

Seham, Mox and Egerer, Seham, Grete. Physiology and Exercise. An Investigation of Cardiovascular Tests in Normal Children with Tuberculosis and Valvular Heart Disease. *Am J Dis Child* 26: 554 [Dec.] 1923.

Cripps, L. D. The Application of the Air Force Physical Efficiency Tests to Men and Women. Special Report Series No. 84. Medical Research Council, London, 1924.

Hambly, W. D., Pembry, M. S. and Warner, E. C. The Physical Fitness of Men Assessed by Various Methods. *Guy's Hosp. Rep.* 75: 388 [Oct.] 1925.

STRICTURES OF CERVIX

To the Editor—I am encountering an unusually large number of complete cervical atresias. In most of these cases cauterization has been done elsewhere but some are of congenital origin. The treatment that I have been carrying out has been to dilate the cervix thoroughly and then place a Chamber's pessary in the canal and leave it there for about six weeks. My results are far from satisfactory. Will you please outline treatment used in the larger clinics. Please omit name and address.

M.D. Georgia

ANSWER—Strictures of the cervical canal, especially partial strictures, are more common than is generally realized. In young women the most frequent causes are infection and instrumentation. The most common infection responsible for stricture is gonorrhea. The most frequent instrumental manipulations that lead to atresia of the cervix are incorrect applications of the electrical cautery and curets and cervical dilators used for dilation and curettement of the uterus. Operations on the cervix also result in strictures in many cases, and occasionally tumors and fibroids block the cervical canal. In older women cervical strictures are usually due to changes that result from old age, the use of radium and carcinoma. Of course, radium and cancer may also produce strictures in younger women.

The most common symptoms of strictures of the cervix are leukorrhea, the passage of tarry blood during menstruation and dysmenorrhea. Not infrequently, pyometra results from a cervical block. As Curtis (*THE JOURNAL*, March 12, 1932, p. 861)

emphasizes, "the otherwise inexplicable sudden appearance of profuse purulent vaginal discharge in a woman beyond the menopause is pathognomonic evidence of cervical stricture."

Prophylactically, strictures may be avoided by the careful use of the electrical cautery, cervical dilators and uterine curets. Women who have had intra-uterine and intra-cervical radium should be checked up at frequent intervals and their cervixes should be gently probed to try to prevent, but more particularly to detect, strictures. A probe should be used especially if there is a profuse discharge after the insertion of radium into the uterus or cervix.

As noted in the query, dilation of the cervix even when followed by the use of a pessary in the cervical canal does not satisfactorily overcome all cervical strictures unless the obstruction is at the external os. If too forcible attempts are made to break down strictures, new ones may be formed which are worse than the original ones. If complete strictures in young women cannot be satisfactorily overcome by means of Hegar dilators, they may be relieved by a Schroeder or Sturmdorf operation. However great care must be used to see that a sufficiently patulous cervical canal is left, otherwise new strictures may form. If the strictures produce symptoms in older women the entire cervix may be amputated or a vaginal or abdominal hysterectomy performed.

PERSPIRATION OF FEET

To the Editor—I should like to know a good treatment for the prevention of excess perspiration of the feet in children. Some children have very excessive perspiration of their feet with a disagreeable odor so that their socks have to be changed sometimes two or three times a day. I am speaking of cases in which there is no associated ringworm and the child is perfectly normal in all other respects. I have treated these by soaking every night in a weak solution of formaldehyde but would be glad to hear of a more effective and less disagreeable treatment.

G. L. JOHNSON, M.D., Englewood, N. J.

ANSWER—The following are effective procedures in the prevention of excessive perspiration and disagreeable odors of the feet in children:

Observe absolute cleanliness.

Bathe the feet once daily for about ten minutes in any of the following solutions: (a) 1 4,000 potassium permanganate; (b) compound solution of cresol three teaspoonfuls to one gallon of warm water; (c) alum one teaspoonful to one pint of water.

Use one of the following antiseptic dusting foot powders freely twice daily: (a) from 1 to 2 per cent salicylic acid in powdered borie acid or (b) from 1 to 2 per cent salicylic acid in equal parts of zinc oxide and talcum. These powders may also be used without the salicylic acid.

Have the shoes large and loose, to increase ventilation. Alternate the shoes daily, airing the used ones.

Change the socks daily.

If these measures fail to control excessive sweating, a strong astringent may be used in addition, such as a 25 per cent aluminum chloride solution, dabbed on the affected parts every third day and allowed to dry.

Röntgen therapy is the best and most satisfactory remedy in obstinate cases.

EFFECTS OF METHANE

To the Editor—Eight Negroes have just recently come under my care who claim that they have a bronchitis as a result of being exposed to marsh gas or methane while working in a cofferdam in June 1933. Physical and roentgen examinations show no acute lesions yet they complain of shortness of breath and some have a slight cough. Complete laboratory work has not been completed to rule out other conditions. Kindly let me know what effect if any marsh gas or methane has on the eyes and respiratory tract. It has been my understanding that marsh gas in a sufficient amount of air would not produce any irritation or damage to the respiratory tract. Will you kindly give me any information in regard to the effects that marsh gas might have on the lungs? Kindly omit name.

M. D. MISSISSIPPI

ANSWER—It is not within reason to believe that exposure in June 1933 to ordinary gas irritants would have produced a bronchitis and other respiratory tract involvement persisting until October or November 1934. Pure methane is without known direct irritant action on the respiratory tract or eyes. It becomes necessary to believe that if any such action was induced, other gases must have coexisted with the methane. It is not unusual for hydrogen sulphide, carbon bisulphide or other sulphur compounds, or other irritants that are not sulphur compounds to be present along with methane. If such substances actually were present, irritation of the eyes, respiratory tract and so on is an expectancy but continuation for more than a year without earlier complaint is open to suspi-

cion. Investigation should be directed to more recent exposures. It is presumable that cofferdam work is wet and consequently that no gross amounts of dust were produced. If, to the contrary, gross exposure to siliceous dusts was provided, the possibility of dust lung disease exists. However, any such disorder may be ruled out by appropriate roentgen examination, which appears already to have been made.

TREATMENT OF SYPHILIS

To the Editor—I have a patient, a man, aged 25, who in September 1933 had a suggestive penile lesion. Within three weeks the blood Wassermann reaction was four plus. Treatment was immediately started: a course of eight intravenous injections of nearsphenamine (0.6 Gm.) being alternated with eight injections of iodobismutol (2 cc.) intramuscularly. Both were given at weekly intervals and no rest periods were allowed between courses. He has now had four courses of nearsphenamine and three of the bismuth compound and is on his fourth of the bismuth compound. His spinal fluid was found to be negative serologically in February 1934. A blood Wassermann test in June showed Kahn negative, no fixation of complement in nonecholesterolized antigen and an unsatisfactory test with cholesterolized antigen. A blood test on October 6 showed Kahn negative, noncholesterolized antigen negative, fixation of complement in cholesterolized antigen two plus. The original blood test confirmed was four plus in all three tests. The patient shows no sign of any physical impairment on complete examination including a thorough neurologic examination. I have intended to complete the fourth bismuth course and give him one more course of nearsphenamine and then take his blood test in three months. Would you say that this treatment is adequate or should I persist until the cholesterolized antigen shows no fixation? What is the significance of the one positive test with this antigen and the two negative i.e. Kahn and nonecholesterolized? I have another patient, a young married woman whose husband contracted syphilis in 1930 and married her in June 1932. In October 1933 on a routine examination a four plus Wassermann reaction was found although the only sign was an onyx-plained dizziness. Her spinal fluid was found to be negative in December 1933. She has received the same treatment as the foregoing male patient except that the nearsphenamine dose had to be lowered because of severe reactions. Her blood test on October 20 was three plus in all three tests. She still shows no clinical evidence of syphilis and there is no more dizziness. Once again is the treatment adequate and how much longer do you estimate treatment will be necessary? How much treatment is necessary before a persistently positive Wassermann reaction may be taken as only evidence of the patient being Wassermann fast? If published please omit name and town. M. D. New York.

ANSWER—The diagnosis of suggestive genital lesions should be made with the dark field, preferably before the blood Wassermann reaction has become positive, as it has been repeatedly shown that treatment begun in the seronegative stage offers the patient the best chance for an early cure. The treatment is outlined has been adequate and according to modern standards which advise continuous rather than intermittent treatment in early syphilis. In all probability the next Wassermann report will show a complete reversal in the cholesterolized antigen. The vagaries of the serologic reports in syphilis are difficult to account for. The cholesterolized antigen, being the more sensitive of the two, is apt to remain positive longer. The interpretation of the Wassermann and Kahn tests should be correlated with the physical observations, and experience has shown the fallacy of placing too great reliance on a single negative test.

In the second case treatment has been adequate but again it is difficult to estimate how much longer treatment will be necessary. There are no exact standards or criteria available that can be used as evidence of the patient being considered Wassermann fast. The inquirer should be congratulated on his ability to administer the large amount of treatment given these patients without straining their physical or financial endurance too much.

ENDOCRINE GLANDS AND DIABETES

To the Editor—I wish to inquire as to the relationship of the other endocrine glands to diabetes mellitus. In advanced cases in which the blood sugar is controlled with difficulty with insulin are there any benefits to be gained by the administration of other gland products, e.g. parathormone? I would appreciate a summary of the literature. Please omit name and address.

M. D. Ohio.

ANSWER—This is a question at present rather difficult to answer. It has been found that the anterior pituitary secretes a diabetogenic principle which is antagonistic to insulin (the pituitary raises the blood sugar, while insulin lowers it). Based on the observation that estrogenic principles (theelin, Amniotin and so on) suppress the secretion of gonadotropic substances by the pituitary, estrogenic substance has been administered to pancreatectomized animals to see whether secretion of the diabetogenic principle might also be reduced (and the blood sugar thereby decreased). This has been found to be the case (Barnes, Regan and Nelson, *THE JOURNAL*, Sept. 16, 1933,

p 926) However, such use of estrogenic substance in clinical cases would be restricted by its effects on the secondary reproductive organs in both female and male. If estrogenic substance should be otherwise indicated in a patient with refractory diabetes, it might be tried. In some cases in which overactivity of the pituitary is suspected, radiation therapy of this organ has been tried but this treatment entails a large element of danger in that selective suppression of only one of the many factors produced by the pituitary would be impossible. Amenorrhea and disturbances of fat metabolism have followed such therapy. In addition of course structures of the central nervous system would be affected to an indeterminate extent.

Recent investigators (Barnes, Scott, Ferrill and Rogoff, *Proc Soc Exper Biol & Med* 31:524 [Feb] 1934) have also implicated the suprarenal medulla in the control of blood sugar (epinephrine, as is well known, raises the blood sugar). Although a reciprocal interrelationship of the suprarenal and the parathyroid glands has been demonstrated (Rogoff, *Science* Oct 5 1934 p 319), the relationship of the latter phenomenon to the blood sugar level is unknown. Administration of parathyroid extract clinically in diabetes such as the inquirer suggests certainly has no sound basis in experimental physiology. Possible chemical applications of these observations are not known.

An extensive series of articles on glandular physiology and therapy, in which all these questions will be authoritatively discussed is now being published in *THE JOURNAL* under the auspices of the Council on Pharmacy and Chemistry.

ENCEPHALITIS AFTER ARSPHENAMINE

To the Editor—I wonder whether you can help me in arriving at a possible diagnosis for the following complication of arsenotherapy. A white woman aged 26 a secundipara whose past medical history and family history are of no importance and who smokes a pack of cigarettes a day and drinks beer occasionally came to the outpatient department with an extensive roseola of secondary syphilis of one week's duration with macous patches in the throat on the umbilicus and on the labia. The primary sore was on the labia. She had a generalized adenopathy and a four plus Wassermann reaction. Neurologic examination at this time showed nothing abnormal. Treatment was started immediately 0.1 Gm. of nearsphenamine being given intravenously. It so happened that the needle slipped out of the vein and only part of the solution was administered the first day making the initial dose 0.1 Gm. One week later she was given 0.15 Gm of nearsphenamine. Two days after this her physician sent her into the hospital because of a severe Herxheimer reaction manifesting itself by extreme swelling of the labia. She was admitted September 29 and we were contemplating discharging her October 1 because the reaction had subsided in the usual manner. However 0.3 Gm of nearsphenamine was administered and the following morning an extensive scarlatinoid rash developed which my associates and I called an eighth day arsenical reaction. We kept her in the hospital in order to observe the skin reaction and it began to clear up two days after its appearance. On the fourth day after the 0.3 Gm of nearsphenamine the patient became drowsy, was very noisy when aroused, vomited, refused to eat and became quite irrational. Although there were no convulsions at any time her body and limbs often trembled considerably. There was no loss of sphincter control. Associated with this there was a fever varying from 99 to 103 and a pulse rate varying from 100 to 120. The stupor and delirium became worse from day to day over a period of four days. There was no real coma at any time. Neurologic examination showed the pupils slightly contracted reacting normally to light and in accommodation and lateral nystagmus. There was no cranial nerve involvement. The deep tendon reflexes were markedly increased and ankle clonus was present. Babinski's sign was negative. The optic disk showed no signs of pressure. Spinal fluid examination showed a cell count of 20 leukocytes per cubic centimeter. The spinal fluid Wassermann reaction was positive in all concentrations; the colloidal gold test gave a second zone reaction; the globulin test was positive. At the first sign of her stupor she was treated with 1 cc of 1:1000 epinephrine hydrochloride intramuscularly every four hours and 1 Gm of sodium thiosulphate intravenously every twenty-four hours. She began to improve on the fifth day following the onset of her stupor and she made an uneventful recovery and was discharged October 15, seven days after admission and eleven days after the onset of the stupor. The only diagnosis of her reaction that offered itself to us was that of a hemorrhagic encephalitis. Could such a diagnosis be justified on such observations? What conditions would offer themselves for a differential diagnosis? With a history of such a reaction is one justified in employing arsenotherapy on this patient at some future time or should one avoid arsenicals and use only the heavy metals? Kindly omit name.

M D Pennsylvania

ANSWER.—Encephalitis following the administration of arsenophenamine has been described and seems to be established. It is difficult to suggest any other explanation for the symptoms and their sequence in this case. Under these circumstances the use of arsenicals seems to be contraindicated. In view of the strongly positive signs of invasion of the central nervous system, the possibility should be considered of inducing fever by inoculation with malaria or otherwise as a prophylactic measure. Thorough treatment with the heavy metals should unquestionably

MIGRAINE WITH HYPERTHYROIDISM

To the Editor—I should be glad to have assistance and a diagnosis of this case. M. J. W., a white man aged 36, complains of feeling all day and tires on the slightest exertion. There has been a long-standing history of severe headaches relieved only by hypodermic injections of morphine one-fourth grain (0.016 Gm.). They occur from six to twelve times a year. The patient is 5 feet 7½ inches (170 cm.) tall and weighs 142 pounds (64 kg.). He has lost about 10 pounds (4.5 kg.) over the course of five years. He sleeps well, does not cough, has no increase in temperature and has no pains except during the attacks of migraine. The rate of the heart is 90 times normally on slight exertion such as jumping up and down lightly fifteen times on one foot; the pulse increases to 130. It is a little slow in returning to its normal range, 90. The blood pressure is 110 systolic, 80 diastolic. The tongue is heavily coated constantly. The bowel function is normal (no laxatives needed). The basal metabolic rate is plus 17. The Wassermann reaction is negative; hemoglobin is 85; there is no leukocytosis. The patient is used to taking four cups of coffee daily in addition to three or four Coca-Colas. He smokes on the average a package of cigarettes a day and uses alcohol slightly. There are no foci of infection. The tonsils were removed in 1928. Roentgen examination of the teeth discloses abscesses. Eye examination reveals that glasses are not necessary. The patient reports that for years he has felt it necessary to drive him with stimulants to do his work which is largely mental with an ordinary amount of physical activity. Any suggestions you may offer in helping me to come to a diagnosis will be appreciated. Please omit name.

M D Kentucky

ANSWER.—The impression obtained from this case report is that in addition to the migraine the patient has a mild hyperthyroidism of the type often associated with adenomatous goiter, continued over a long period. The points in favor of this impression are the loss in weight, the easy fatigability, the tachycardia, the slightly elevated basal metabolic rate and the inability to sleep well. The increased cardiac liability, or even myocardial impairment as indicated by the decreased exercise tolerance, might well be the cardiac manifestations of a long-continued thyrotoxicosis of mild grade, although the pulse pressure is not increased.

Other features of thyrotoxicosis which if present would confirm the diagnosis are increased tolerance to cold, decreased tolerance to heat, moist warm hands, fine tremor and a tendency to perspiration.

The absence of fever and the maintenance of a normal hemoglobin level are compatible and would discredit the possibility of a chronic infection such as tuberculosis as a likely cause for the illness.

In view of the migraine, the possibility of an anxiety neurosis with chronic mental fatigue and sympathetic instability should be considered. Such a condition might conceivably produce the symptoms and signs described but should not be difficult to differentiate from hyperthyroidism. If this cannot be done satisfactorily, the effect should be observed of a program of increased rest and correction of the faulty habits mentioned.

ENCEPHALITIS TUMOR OR HYPOLYCEMIA

To the Editor—A woman aged 26 married with no children began to be troubled six months ago with a progressive lethargy during which there occurred attacks of vomiting. The outstanding symptom is yawning and inability to remain awake although between attacks the patient is extremely well and symptom free. Her past history is negative with the exception of a hypothyroid condition (basal rate minus 26 six months ago) which was corrected by the administration of one-half grain (0.03 Gm.) of thyroid and 5 grains (0.3 Gm.) of ovarian extract three times a day. After six months time her basal rate was plus 6. She does not complain of headache or abdominal distress nor is there tenderness elicited at any point in the abdomen. Her fasting blood sugar was 100. Owing to the extreme lowness this was questioned but a blood sugar tolerance test proved that there was a hypoglycemia which is probably due to a hyperinsulinism. The carbon dioxide combining power was 14. The blood chlorides were 400 and blood urea 14. On the administration of 300 cc of a 20 per cent dextrose solution the lethargy was completely controlled as was the vomiting. This appears to be a case which can be held symptom free on the administration of dextrose intravenously although sugars by mouth apparently have no effect. Could you advise to the possibilities of a diagnosis as urinalysis, blood count and roentgen examination of the skull are also negative? As the patient is in the hospital at the present time I would appreciate an early response. Please omit name and address.

M D Delaware

ANSWER.—Despite the low blood sugar in this case, the general picture does not suggest hyperinsulinism. Patients with a spontaneous hypoglycemia are almost always relieved by taking dextrose by mouth, vomiting is not a characteristic symptom, and blood chlorides are not reduced. It is possible that the effect obtained by the intravenous injection of dextrose may have been due to its action as a hypertonic solution. The complaints are somewhat suggestive of encephalitis or tumor, even though a positive diagnosis may not be possible at the present time. Stramonium leaf or opium might be tried.

Book Notices

The Complaint Pediatrician. Practical Diagnostic Therapeutic and Preventive Pediatrics for the Use of Medical Students Interns General Practitioners and Pediatricians. By Willburt C. Davison M.D. D.Sc. M.D. Professor of Pediatrics, Duke University School of Medicine. Adaptation of the Title Page of *The Complaint Angler* by Izaak Walton 1613 (cloth Price \$3.75, Various pagination Durham N.C. Duke University Press 1934)

This author has audited pediatrics. He has published his statement in the form of a modified thesaurus, encyclopedia, index and telephone directory combined. The material within the individual chapters is arranged alphabetically. Each subject is a serially numbered section with black faced title, all caps subtitles, first letter caps for subdivisions, lower case letters for supporting material, and daggers, dashes and asterisks to designate the frequency of a symptom or disease, besides small black faced material numbered and lettered subheads, tabulations, prescriptions and recipes. The chapters include first a short but explicit road map type of description telling how to use the book. Then follow chapters on symptoms and signs, diseases, differential diagnosis and treatment, preventive measures, administration of fluids and blood, feeding and special diets, drugs and prescriptions and finally laboratory methods. The pages are not numbered. For greater facility in using the book as a rapid fire reference work, the author has wisely chosen to number the sections. The first section is numbered 1957 although there are not 1957 sections in the book. For instance, the chapter on symptoms has sections 1-79, diagnosis and treatment 100-900, prevention 1300-1390, fluids 1401-1425, diets 1501-1595, drugs 1601-1773, laboratory methods 1801-1957. However, the preface and introduction are designated pages 1 to 1. There are innumerable cross references.

The scope of pediatrics has been ingenuously reduced to mathematics. The author says that there are 307 conditions of which only 100 are important. Of these thirty seven which cause 56 per cent of the deaths in children can be prevented. The sixty-three responsible for 21 per cent of pediatric deaths respond to adequate therapy. He insists that every doctor can diagnose and treat successfully the sixty-three curable as well as twenty of the thirty-seven preventable. The other 207, causing 23 per cent of the deaths, can be diagnosed but since the patient succumbs or recovers regardless of therapy, he feels that they may be disregarded.

From this analysis it is readily seen that the author has nailed down the pinpoints of pediatrics. The chapters on symptoms and diagnosis contain the essential facts, but the tabulations are too brief and staccato to give a picture of disease. The student cannot learn pediatrics for the first time from this kind of work. Nevertheless, the sections on treatment, fluids, diets, prescribing and laboratory methods are invaluable. The author has succeeded in his intention to concentrate all the facts and helps in pediatrics in an extremely simple way so that his comparatively tiny work might well be used as a rapid reference work in the office and as a great help in the bag. The cover is light colored cloth and should be covered with oilcloth as it will not stand the mussy hands that will constantly thumb its pages.

The author has gone to Izaak Walton for the inspiration of his title and the appearance of his title page. He must have had a lot of fun compiling this cross index pediatricus. There is nothing else like it in English.

Principles in the Treatment of Inflammation. By T. E. Hammond, F.R.C.S. Assistant Surgeon, The Royal Infirmary, Cardiff. Cloth Price 10/6. Pp. 209. London: H. K. Lewis & Company Ltd. 1934.

The thesis of this book is just the opposite of the theses so generally and fulsomely exploited at 'commencement day' orations. These lead the medical neophyte to believe that the 'wonderful' progress of medicine has made him master over disease and that he is now entering on a victorious career of curing human ills. This book by a World War military surgeon and seasoned clinician might be recommended as a good antidote to the dangerous cocksureness thus engendered. Hammond points out that physicians do not understand it all, that disease generally arises we know not why, and that

much depends on the patient's 'constitution,' a matter about which little is known. "In few diseases has treatment been more irrational than in inflammations. Inflamed fingers are still immersed in antiseptic solutions, though few believe that these have any action and some even think that they do harm. But few are prepared to say so, as it is felt that, where the work of Lister is concerned, this amounts to blasphemy. The practitioner is too often governed by the feeling that he must do something. He is afraid that his reputation is at stake if the case comes to the postmortem room without something having been done for some one may suggest that the patient would have lived had an incision been made. It is apt to be forgotten that an incision at the wrong time jeopardizes many a life for it flares up the disease and takes away the patient's only chance. Had nature been left alone, the life might have been saved. Resistance is the most important factor in the cure of bacterial disease. There is a definite risk in incising before pus has formed. Curettage of sinuses is being abandoned as the results are so poor. In incomplete abortion a foreign body is beneficially removed by curettage of the uterus. Otherwise the operation is simply a money-making stunt.

It may be necessary to remove the tonsils and adenoids if they obstruct respiration or if they are full of pus. Otherwise it should be kept in mind that tonsils and adenoids become enlarged only when the resistance factor is impaired. It is much better to direct treatment toward the cause of their enlargement. It is just as rational to attempt to cure gout by removing a uratic deposit as it is to try to cure a patient of chronic bacterial disease by removing the affected organ.

Today ability to operate is being confused with the practice of surgery. A thoughtful perusal of this book, dedicated to the Battalion Medical Officers of the Great War, possibly not without a certain amount of grim humor, would go a long way toward making surgery more rational and safer.

The author laments that he can discover in recent work so little of value at the bedside of the patient. 'Scientists forget that they are working on animals in whom disease is artificially induced. Before it started the constitution was sound and the resistance factor was adequate. When this is the case recovery takes place as soon as the exciting cause ceases to act. If scientists want a disordered constitution on which to experiment, why do they not go to sick animals. There are any number of these.

When scientists can put right animals in whom disease has appeared as in man, we know not why, the medical profession will listen more eagerly to their claim.

Much of our failure today, no doubt, is due to the fact that research workers have left the bedside of the patient and are now content to work in laboratories.'

The Pneumonokonioses (Silicosis). Bibliography and Laws. By George G. Davis, M.D., Associate Clinical Professor of Surgery, Rush Medical College, University of Chicago. Ella M. Salmonsen, Medical Reference Librarian, The John Crerar Library, Chicago, and Joseph L. Earlywine, Attorney at Law, Chicago. With a foreword by E. R. Le Count, M.D., Professor and Chairman, Department of Pathology, Rush Medical College, University of Chicago. Cloth Price \$7.50. Pp. 482. Chicago: Industrial Medicine Inc. 1934.

Agricola in 1556 referred to dusts in his 'De re metallica', likewise, late in December 1933, Sappington commented on the problems of dust in relation to disease. In the intervening 377 years at least 2,766 other publications were made, related directly or indirectly to the influence of dusts on living organisms. The citation of these hundreds of publications with many types of cross references, together with a large section devoted to compensation laws, make up the contents of this large publication. By its authors it is described as 'a reference book designed for the permanent convenience of physicians, surgeons, lawyers, industrial executives, librarians, journalists, engineers, trade association officials, student and research workers.' The amount of labor expended manifestly was enormous—perhaps out of proportion to the extent to which the book will be applied. For the industrial hygienist, whether physician, engineer or other public health worker, the book provides both a historical background and the most recent concepts as to the significance of the various types of dusts in human economy. For attorneys connected with the adjudication of claims for dusty lung diseases, it will furnish data on almost any conceivable aspect of such disorders. Librarians will be saved many hours of compilation work through the presence of the book on

their shelves. For the average practitioner who does not delve into medical history and who may not be concerned with dusty lung diseases, it holds no promise of great usefulness. A thorough reading of the book alone will in no wise equip a physician either to recognize or to control silicosis or any other form of pneumoconiosis. The volume is what it purports to be—a pure bibliography, with citations of compensation laws. At the outset it gets off to a bad start through the language of its title. Although silicosis is the chief form of pneumoconiosis, it is improper to imply, as the title does that silicosis is the pneumoconiosis or vice versa. Such ambiguities naturally are the outgrowth of the compilation of highly technical materials jointly by a professor of surgery, a medical librarian and an attorney at law.

Prolapsus du rectum. Etude clinique traitement résultats éloignés. Par Carrasco. Extrait du Professeur Hartmann. Paper. Price 75 francs. Pp 106 with 41 illustrations. Paris. Masson & Cie 1934.

This monograph, by a former assistant of Professor Hartmann, reviews the subject of prolapse of the rectum from the year 1903 when Lenormant's thesis on the same subject was published. The work is well printed and illustrated and has a large bibliography. The various types of prolapse and the pathologic and anatomic factors favoring their origin are those commonly accepted and described in all textbooks. A great variety of methods of treatment are described and illustrated, and in many instances mortality figures and end results are given. Unless one had had considerable personal experience in selection of the method of treatment the variety of suggestions would be confusing. Cauterization, injection of sclerosing substances, methods of excision and suspension and plastic operations on the perineum are all considered under operative treatment. Many case reports illustrate the methods used. The conclusions of the author are excellent and are the only truly authoritative matter in the monograph. He emphasizes the fact that prolapse of the rectum in children is generally of the mucosa alone and will heal itself spontaneously in most instances if conservative management is adopted with particular attention to proper elimination and diet. In adults however conservative management usually fails and more radical measures are necessary. Proper selection of measures depends naturally on the type of prolapse, the etiologic factors in existence and the condition of the patient. Here one may choose from many operations. The multiplicity of methods indicates that not all is well with the results. For intussusception of the sigmoid into and through the rectum some type of abdominal suspension and obliteration of the culdesac is necessary. In mucosal prolapse or true prolapse of the rectum the method described by Delorme and Rehn has given excellent results. However the choice of many types of excision of mucosa suspension of the bowel or plastics on the perineum are given. The monograph makes itself an excellent book of reference on the subject.

Diseases of the Rectum and Colon and Their Surgical Treatment. By J. P. Lockhart Mummery. FRCS. MA. MB. Senior Surgeon to St. Mark's Hospital for Cancer, Fistula and Other Diseases of the Rectum etc. Second edition. Cloth. Price \$10. Pp 605 with 250 illustrations. Baltimore. William Wood & Company 1934.

During the eleven years that elapsed since the last edition of this work knowledge of the diseases of the rectum and colon has shown extensive advances, particularly in the field of pathogenesis and treatment of various lesions of this portion of the alimentary tract. Hence a large part of the book had to be entirely rewritten, several new chapters have been added, one of them dealing with precancerous conditions. The arrangement of the subjects described has been altered in such a manner that the first part of the book is devoted to diseases of the rectum and anus while diseases of the colon have been placed in the second part. A new feature consists of photographic reproductions of operations. The advantage of such illustrations over schematic drawings is subject to discussion. The book represents mainly a record of the author's own experience and this fact must be kept in mind when noting that certain lesions are not mentioned at all or are described in an inadequate manner. For instance, an American reader will miss chapters on amebic dysentery and lymphogranuloma inguinale among fluids used for injections of hemorrhoids,

quinine urea and sodium morrhuate are not mentioned, recent advances in the surgery of the cancer of the large intestine, e. g., the use of vaccine for prevention of postoperative peritonitis, as well as new technical details, did not receive due consideration. However, such omissions are comparatively slight and do not detract from the value of this authoritative work which is profusely illustrated and contains a wealth of valuable material, presented in lucid sequence and a concise manner by a man with a large experience in this field.

Strümpell Seyfarth Lehrbuch der speziellen Pathologie und Therapie der Inneren Krankheiten für Studierende und Ärzte. Bände I II. Von Dr. med. et phil. C. Seyfarth a. o. Professor (für Innere Medizin) an der Universität Leipzig. Thirty first and thirty second edition. Paper. Price 48 marks. Pp 880 with 101 illustrations. 980 with 270 illustrations. Berlin. F. C. W. Vogel 1934.

Since the death of Adolf Strümpell in 1925, this most popular German textbook of internal medicine has been edited and revised by his former co-worker Seyfarth. It seems that the old "Strümpell" has lost nothing of its popularity, as seven new editions were necessary after Strümpell's death. The thirty first and thirty-second editions contain a few newly written chapters and others partially rewritten and brought abreast of the latest state of our knowledge. Among them may be mentioned Bang's disease and tularemia, with special emphasis and reference to the bacteriologic examination, and hypertension and hypotension in which the futility and also the dangers of some therapeutic measures are stressed. There is a brief chapter on Buerger's disease. In the treatment of peptic ulcer alkalis and atropine still maintain their important place. Excellent therapeutic results are reported by the author with the feeding experiments through the permanent duodenal tube in more than 300 cases of peptic ulcer. Osteitis fibrosa (Recklinghausen) and osteitis deformans (Paget) are taken up as strictly separate diseases the former being due to parathyroid disorder and characterized by the disturbance in the calcium metabolism while the latter is of unknown etiology without any disturbance of calcium metabolism and not influenced by parathyroidectomy. The chapters on psychoneurosis, hysteria and neurasthenia are fully revised and thoroughly discussed. The last chapter deals with intoxications. In order perhaps to make a modern German textbook of internal medicine complete this chapter contains a section on war gas poisoning with a classification of the poisonous gases used during the last war and a thorough description of the symptoms and therapeutic measures.

The Heart Visible. A Clinical Study in Cardiovascular Roentgenology in Health and Disease. By J. Polevski. M.D. Attending Physician and Cardiologist, Newark Beth Israel Hospital. Cloth. Price \$5. Pp 401 with 122 illustrations. Philadelphia. F. A. Davis Company 1934.

This small volume intended by the author for the roentgenologist, cardiologist and clinician has in it much of value and fills a definite hiatus in the American literature. It offers an intelligent compendium for the cardiologist or clinician who finds it inconvenient to consult the foreign textbooks or review the extensive scattered literature in English. Dr. Polevski covers the details of the normal and abnormal roentgen observations of the heart, pericardium and great vessels. He also explains clearly the technical procedures involved in making a comprehensive roentgen examination of the heart and great vessels. He has an adequate conception of what can be elicited by this method and a proper deference to the importance of correlations with clinical examinations. The material that he offers is sound, but in several instances one might take exception to the views propounded. The terms "mitral" and "aortic" heart are used loosely. It is not advantageous to divide all abnormal heart contours into these two types, as the author himself admits. Too much significance is attached to the small heart especially in view of the fact that true hypoplasia is a relatively rare condition. A certain looseness of expression that leads to such description as the unexpanded lungs of infancy and fatty infiltration of the myocardium is to be deplored. Exception can be taken to the author's explanation of a decrease in inspiratory size of failing hearts as partly due to the compressing effects of the expanding lung on the heart. The ideas expressed by the author that the darkness of the shadow of the syphilitic aorta is due in part to atheromatosis of wall and that erosions caused by aneurysm simulate the spine of caries

cannot be accepted without qualification. However, these minor faults do not detract from the general excellence of the book. It would have been better if the illustrations had been negatives and not positives, but they are relevant and are adequate for the text.

Infantile Paralysis. By George Draper M.D. Associate Professor of Clinical Medicine, College of Physicians and Surgeons, Columbia University. Cloth. Price \$2. 1p. 167 with 24 illustrations. New York & London: H. Appleton (Century Company) Inc. 1935.

The author of this book is well known for his splendid contributions to the study of constitution and its relation to disease. Few other medical authors are better qualified by virtue of medical training and philosophic background to present to the intelligent lay public a short and comprehensive discussion of a subject so diverse in its manifestations. This is not an ordinary treatment of the subject but a scholarly and dispassionate presentation filled with useful scientific information about the disease and punctuated with enough philosophical reflection so that the reader not only learns but gains a certain amount of reassurance. The author has anticipated the numerous questions which the lay reader will want to know concerning the nature of the disease, its prevention and what can be done after the disease is contracted. Any treatise written by this author without consideration of aspects of inherent susceptibility would be to the reader's loss. However, this subject is clearly presented in his discussion of individual susceptibility. Here he considers that mysterious property possessed in varying degrees by every individual, the presence of which endows resistance and the absence of which invites infection. In the final chapter on the outlook and the healing, Dr. Draper gives a lucid exposition to the usual questions asked by the parents of a child afflicted with the disease. The book is highly recommended to the public as an authoritative and scholarly account of infantile paralysis as well as a textbook that will meet needs of parents whose children have become afflicted.

Fundamentals of Dairy Science. By Associates of Lore A. Rogers in the Research Laboratories of the Bureau of Dairy Industry, United States Department of Agriculture. American Chemical Society Monograph Series. Second edition. Cloth. Price \$6. Pp. 616 with illustrations. New York: Book Department, Reinhold Publishing Corporation. 1935.

This scientific and technological monograph prepared by present or former members of the staff of the Research Laboratories of the Bureau of Dairy Industry and published under the auspices of the American Chemical Society presents to advanced students and research workers a well digested survey of more important knowledge in the field of dairy science: basic data, fundamental observations and unbiased discussions of research. The subject matter is arranged so as to bring together topics of similar scientific classification rather than under the usual headings of specific dairy products: part I being devoted to the constituents of milk, part II to the physical chemistry of milk and milk products, part III to the microbiology of milk and milk products, and part IV to the nutritional value of milk and milk products, and the physiology of milk secretion. The monograph should stimulate and guide and facilitate research along those lines in dairy science which need most development to maintain a proper balance of knowledge in the whole field. To each chapter is appended a list of important references to the literature. This work will be a valuable addition to the reference libraries of all interested in the present scientific status of dairy science.

Die Serum β -Lysine und die antibakterielle Immunität gegen die davon beeinflussten Mikroben. Von Professor Dr. Alfred Pettersson. Karolinisches Institut Stockholm. Paper. Price 5 marks. Pp. 75. Jena: Gustav Fischer. 1934.

This monograph deals with bactericidal substances in serum that differ from the bacteriolysins mainly in being more resistant to heat. The author who has done a great deal of work on these substances, calls them serum- β -lysins to distinguish them from the less heat resistant lysins which he calls serum- α -lysins. The properties of the serum- β -lysins, the bacteria that are susceptible to their action, and the immunity against some of these bacteria are discussed. The monograph will interest all those who are working with the bactericidal actions of the blood and its components. The literature in question is reviewed thoroughly.

Cataract: Its Etiology and Treatment. By Clyde A. Clapp M.D. F.A.C.S. Associate Professor of Ophthalmology, Johns Hopkins University. Cloth. Price \$4. 1p. 254 with 92 illustrations. Philadelphia: Lea & Febiger. 1934.

The author has assembled the pertinent facts pertaining to the lens and arranged the material in a logical sequence. Dr. Ida Mann has written the first and second chapters, on the development and comparative anatomy of the lens. The foregoing, with the material on anatomy, growth, physiology, chemistry and anomalies, are contained in the first seven chapters (about one fourth) of the book. The remaining eighteen chapters deal with cataracts. The author in turn writes of the pathogenesis of all cataracts and discusses congenital traumatic secondary complicated and senile cataracts. He outlines but gives little credence to the nonoperative treatment of cataracts. The remainder of the book except for chapter XVI which is on couching and is of historical interest and the last two chapters, on dislocations of the lens and on aphakia with its treatment deals with the various types of cataract operations as well as the preparation for the operation and the postoperative care. He has included the electrodiaphanous method of Lacarrere. There are numerous illustrations of the various methods of suturing. In the chapter on anesthesia he gives the various methods for producing akmesia, but the technique for this important procedure is too brief. In the preface the author states that a complete bibliography has not been attempted. The work is distinct and significant and one can readily agree with Dr. Wilmer, who in his foreword wrote: 'Dr. Clapp has succeeded admirably in a very difficult task of placing between these covers a vast amount of interesting and useful information. It should be welcomed by students and by practitioners of ophthalmology.'

Tests for Respiratory Efficiency. By Alan Monerleff. Medical Research Council Special Report Series No. 198. Paper. Price 1s. Pp. 62 with 7 illustrations. London: His Majesty's Stationery Office. 1934.

The demand for clinical and laboratory methods for quantitative evaluation of functional efficiency of organs or systems is in ever increasing demand. Both surgeon and physician desire to assess the degree of impairment with which they have to deal. In this monograph the author sets forth in a concise manner the various methods employed in testing respiratory efficiency. He concludes that no one test can be relied on and that in order to gain a useful estimate of respiratory function the patient's vital capacity, ventilating efficiency and expiratory force must all be studied. The author does not settle the question but his work is critical and stimulating. It will be read with interest by all those interested in estimating the efficiency of the respiratory apparatus. The report will be of special interest to those engaged in insurance work and those concerned with passing on the medical qualifications of individuals in occupations involving strain on the respiratory systems as aviators, deep sea divers, and athletes engaging in competitive sports.

F. J. Shepherd—Surgeon. His Life and Times. By William Boyman. Howell. Cloth. Price \$3.50. Pp. 251 with illustrations. Toronto & Vancouver: J. M. Dent & Sons Ltd. 1934.

About Dr. Shepherd as a central figure Dr. Howell has constructed in an interesting manner the story of medical practice and institutions in Montreal during the period from 1869 to 1929. With the substitution of different names, the same narrative might be applied to the course of medical affairs in other cities of Canada and in numerous ones in the United States. At the beginning of this period, medical schools in America were inferior to those in Europe and the teachers were usually general practitioners who expected their positions to aid them in their private business. Among these teachers were some talented and determined young men who like Dr. Shepherd continuously worked for the gradual betterment of medical education and medical institutions. Dr. Shepherd was an enthusiastic teacher of anatomy for more than thirty years. Like him most of the surgeons of the last quarter of the nineteenth century came up through anatomy. These younger men were the ones who accepted and applied antiseptic and aseptic methods and they had the courage and skill to extend the field of operative surgery to the internal cavities of the body. Dr. Shepherd's birth and early life in the country gave him an

opportunity to develop a love for natural beauty and a fondness for fishing. The former shows in his interest in art and in his large private collection of critically selected pictures. He traveled extensively and was an active participant in medical societies at home and abroad. Dr. Howell has performed a valuable service in outlining so well the trend in America of medical matters during the last quarter of the nineteenth and the first quarter of the twentieth century and in giving such a satisfactory glimpse of conditions and persons in Europe at the same time. He has been fortunate in having as his central figure a man who so well exemplified what was best among his contemporaries. The volume closes with a list of the writings of Dr. Shepherd and an excellent index.

Poliomyelitis. A Handbook for Physicians and Medical Students Based on a Study of the 1931 Epidemic in New York City. By John F. Landon, M.D., Attending Physician, Willard Parker Hospital, New York, N. Y., and Lawrence W. Smith, M.D., Pathologist, Willard Parker Hospital, New York, N. Y. With a section on the Orthopedic After Care of the Disease. By Harry deN. Hough, Jr., M.D., F.A.C.S., F.A.A.O.S., Attending Orthopedic Surgeon, Shiloah Hospital for Crippled Children, Springfield, Mass. Cloth, Price \$3. Pp. 275 with 18 illustrations. New York: Macmillan Company, 1934.

The aim of this book is to present a short treatise on the subject of poliomyelitis chiefly for the physician in practice. While a number of textbooks are available on this subject few works present the modern developments of the knowledge of this disease in such a comprehensive and compact form. The data presented are recent and carefully evaluated with the background of an exceptionally large clinical and pathologic experience in the epidemic of poliomyelitis that occurred in New York City in 1931. The book treats almost every phase of the subject in a scholarly and impartial manner. The chapter on pathology is particularly lucid and is based on the data obtained from nearly 100 postmortem examinations. The text is well illustrated and contains a valuable list of current bibliographic references. The modern aspects of treatment such as serum therapy, the use of respirator and after care are carefully evaluated from a practical point of view. The appendices on nursing care, aseptic technique and methods of serotherapy are a valuable addition. The book is highly recommended to the practitioner and student of medicine as a concise and practical handbook on the subject of poliomyelitis.

On Serological Tests for Syphilis with Very Small Amounts of Patient's Serum. By E. J. Wyler, M.C., M.D., Reports on Public Health and Medical Subjects No. 74, Ministry of Health Paper. Price 6d. Pp. 20 with 3 illustrations. London: His Majesty's Stationery Office, 1934.

In this bulletin the author who is chief serologist in the Ministry of Health, gives technical details for performing the Wassermann test as previously described by the same author, the Kahn test, the Memick test and the recently reported Rosenthal method, by using minute amounts of serum. Microtechnics are desirable in the case of infants from whom it is often difficult to obtain amounts of blood sufficient for regular tests. The bulletin should be of interest to laboratory workers.

The Practitioners Library of Medicine and Surgery. Volume VII, Pediatrics. [George Blumer, supervising editor.] Cloth, Price \$10. Pp. 1211 with illustrations. New York & London: D. Appleton-Century Company, Inc., 1935.

Since pediatrics is essentially internal medicine as applied to the child, much of the material in this book duplicates information already made available in some of the previous volumes of this excellent system. However, the approach to each of the subjects is made from a special point of view and the studies are necessarily chosen from the field concerned. The volume is therefore a most useful one and constitutes virtually a textbook on pediatrics written particularly with the general practitioner in mind. The various chapters concern the development of the child and its hygiene, nutrition and diets and thereafter a consideration of the diseases of the child classified according to the body system and organs, proceeding then to discussions of the various infectious diseases, and concluding with poisoning and worm infestation. This volume more than previous contributions, lacks adequate illustration. It is, however, excellent in its discussions and quite up to date. The classic outlines of Osler are followed in the systematic approach to the various topics. Each of the chapters is supplemented by bibliographic notes.

An Atlas of Infant Behavior. A Systematic Delineation of the Forms and Early Growth of Human Behavior Patterns. By Arnold Gesell, Ph.D., M.D., Sc.D., Director of the Clinic of Child Development and Professor of Child Hygiene in Yale University. Volume I, Normative Series. In collaboration with Helen Thompson, Ph.D., and Catherine Strunk Amatruda, M.D. Volume II, Naturalistic Series. In collaboration with Alice Virginia Kellier, Ph.D., Frances Lillias, M.D., and Jessie Jarvis Carlson, Ph.D. Leather. Price \$25 per set of 2 volumes. 1 p. 921 with 3200 illustrations. New Haven: Yale University Press, 1934.

The authors of this work have charted the behavior of the infant with some 3,000 photographs. Thus they indicate his various postures, his use of his senses, his relationships to his environment and the gradual growth of his compliance with social custom and manner. For the purpose a photographic dome was prepared especially equipped with the necessary materials. It thus becomes possible for physicians, psychologists, biologists and others to study in the minutest detail the development of the infant physically and mentally.

The second volume concerns the natural day of an infant under conditions in the home giving in the minutest detail the steps involved in spoon feeding and breast feeding, also the use of the bottle and the cup, the bath, the baby's play, and its progress in walking, growth and in other ways. The interested professions will find many uses for this material.

Miscellany

NUMBER AND GEOGRAPHIC LOCATION OF NEGRO PHYSICIANS IN THE UNITED STATES

JULIAN H. LEWIS, PH.D., M.D.
CHICAGO

For a special purpose I recently accumulated the names, geographic location, medical school and year of graduation for the Negro physicians practicing in the United States in 1932. The facts were obtained from the most recent directory of the American Medical Association and from graduation lists from the various universities. The resulting data, when compared with similar information for the general population, present some interesting similarities and contrasts.

Nearly 12 million people, or about 10 per cent of the population in the United States, are classified as Negroes, whereas only 4,000 or 2.5 per cent of the licensed physicians in the

TABLE 1—Number and Percentage of Negro and White Population and Physicians in the United States in 1932 and Population per Physician

	Physicians		Population		Population per Physician
	Number	Per Cent	Number	Per Cent	
Negro	3,985	2.5	11,900,613	9.7	9,888
White	162,545	97.5	110,886,903	90.3	785
Total	166,530	100.0	122,787,516	100.0	750

country are Negroes. There is one Negro physician for each 3,000 Negroes based on the 1930 census data as compared with a ratio of 785 persons per physician for the United States as a whole.

The Negro physicians are unevenly distributed throughout the country as compared with the Negro population. Although the Southern states contain more than 85 per cent of the Negro population, scarcely 60 per cent of the licensed Negro physicians practice medicine in this area. The ten Northern states with 30,000 or more Negroes have only 18 per cent of the Negro population but nearly 40 per cent of the Negro physicians.

From the Otho S. A. Sprague Memorial Institute and the Department of Pathology, University of Chicago.

The ratio of Negro population per physician is 3,824 in the Southern states but there is considerable variance among them. Mississippi has one Negro physician to each 14,000 Negroes. This is followed by ratios of approximately 9,600 for South Carolina, 8,000 each for North Carolina and Alabama, 6,700 for Louisiana and 5,500 for Georgia. In contrast the following Southern states show larger proportionate numbers of

TABLE 2—*Negro Population, Negro Physicians and Population per Physician According to Geography Areas and in Cities with More Than 50,000 Negro Population in 1932*

	Negro Population 1930	Negro Physicians 1932	Population per Physician
Seventeen Southern states	9,429,813	2,401	3,824
Ten Northern states with 30,000 or more Negro population	2,171,827	1,382	1,571
Twenty-two other states	10,961,107	1,671	6,500
Total	31,352,027	6,454	4,856
Cities with 50,000 or more Negro population	1,877,703	1,320	1,413

Georgia, Mississippi, Alabama, North Carolina, Texas, South Carolina, Louisiana, Virginia, Arkansas, Tennessee, Florida, Maryland, Missouri, Kentucky, District of Columbia, West Virginia, Oklahoma, Pennsylvania, New York, Illinois, Ohio, New Jersey, Michigan, Indiana, California, Kansas, Massachusetts, New Jersey, New York, Chicago, Philadelphia, Baltimore, Washington, D. C., New Orleans, Detroit, Birmingham, Memphis, St. Louis, Atlanta, Cleveland, Pittsburgh, Richmond.

Negro physicians among the Negro population. The ratio of Negro population per physician is 1,500 for Tennessee, 1,000 for Missouri, and less than 500 for the District of Columbia.

Among the ten Northern states with 30,000 or more Negroes the ratio of Negro population per physician averages about 1,600 to 1. Illinois leads with 332 Negro doctors and is the only state with a ratio of less than 1,000 Negro population per physician. The states of Pennsylvania and New York show much less concentration of Negro physicians with ratios of

TABLE 3—*Negro Population, Negro Physicians and Population per Physician in Seventeen Southern States, 1932*

State	Negro Population 1930	Negro Physicians 1932	Population per Physician
Georgia	1,071,120	190	5,492
Mississippi	1,009,118	71	14,221
Alabama	914,834	116	8,140
North Carolina	918,647	114	7,882
Texas	834,964	215	3,907
South Carolina	603,681	83	9,562
Louisiana	706,326	116	6,082
Virginia	600,160	180	3,334
Arkansas	478,462	100	4,782
Tennessee	411,640	108	3,801
Florida	431,828	109	3,902
Maryland	266,379	111	2,400
Missouri	233,640	216	1,082
Kentucky	266,040	111	2,400
Oklahoma	172,198	87	1,979
District of Columbia	112,068	271	460
West Virginia	114,803	63	1,824
Total	9,429,813	2,401	3,824

2,552 and 2,281 respectively. The four states Pennsylvania, Ohio, New York and Illinois contain about 2,000,000 Negroes and 900 Negro physicians. The states of Georgia, Mississippi, Alabama and North Carolina contain twice as large a Negro population and but half as many Negro physicians.

There is a concentration of Negro physicians in large cities both in the North and in the South, regardless of whether there is a proportionately large Negro population. The three cities in the United States with more than 200,000 Negro population are New York, Chicago and Philadelphia with ratios respectively of 2,200, 800 and 2,100 Negroes per physician. Next in line as to Negro population are Baltimore, Washington, D. C., and New Orleans, generally regarded as Southern cities with ratios respectively of 1,700, 500 and 2,400

Partly because of the location of Howard University, Washington, D. C. has nearly twice as many Negro physicians as New York, although it has scarcely one-third as large a Negro population. Likewise, Nashville, Tenn., with 40,000 Negroes, the home of Meharry Medical College, has seventy-seven Negro physicians, although New Orleans, with a Negro population of 130,000 reported fifty Negro physicians in 1932.

A number of large Northern cities with very limited Negro populations report ratios of less than 1,000 Negro population per physician. Among these cities are Los Angeles, Oakland, Calif., Denver, Portland, Ore., Spokane, Wash., Buffalo, Erie and Scranton, Pa., and Milwaukee.

Most of the 4,000 Negro physicians practicing in 1932 were graduates of Southern medical schools. Of the total, 69 per cent came from Meharry Medical College and Howard University. Another 11 per cent were from various Southern medical schools, most of which are now out of existence.

TABLE 4—*Negro Population, Negro Physicians and Population per Physician in Ten Northern States Having 30,000 or More Negro Population in 1930*

State	Negro Population, 1930	Negro Physicians, 1932	Population per Physician
Pennsylvania	431,247	169	2,552
New York	412,814	181	2,281
Illinois	328,902	332	991
Ohio	100,004	208	1,480
New Jersey	290,129	139	2,087
Michigan	160,423	117	1,448
Indiana	111,682	70	1,617
California	81,048	75	1,081
Kansas	66,344	30	2,211
Massachusetts	22,365	47	471
Total	2,171,827	1,382	1,571

Northern medical schools graduated 14 per cent and for 6 per cent the names of the institutions were not determined from the study.

From the available data certain general statements appear to be justified concerning the number and location of Negro physicians. There are about one fourth as many Negro physicians for the population as total physicians for the total population. If the Negro population were dependent exclusively on the services of Negro physicians, it would be impossible for them to receive adequate medical care.

TABLE 5—*Negro Physicians in Fourteen Cities Having Over 50,000 Negro Population*

City	Population	Physicians	Ratio
Brooklyn and New York	341,990	151	2,260
Chicago	233,903	287	815
Philadelphia	210,599	104	2,111
Baltimore	142,100	80	1,671
Washington, D. C.	132,008	271	487
New Orleans	129,032	53	2,445
Detroit	120,066	68	1,765
Birmingham, Ala.	99,077	26	3,808
Memphis, Tenn.	90,000	70	1,285
St. Louis	83,580	54	1,532
Atlanta, Ga.	80,070	51	1,569
Cleveland	71,899	50	1,438
Pittsburgh	64,963	21	3,092
Richmond, Va.	62,366	27	2,308
Total	1,877,703	1,320	1,413

Negro physicians tend to concentrate in the large cities, regardless of whether there is a proportionate concentration of Negro population. This is true for both Northern and Southern cities, although there are many more Negro doctors proportionately in the Northern states and cities. The ratio of Negro physicians to population is lower in every state and city than the ratio of total physicians to total population.

Medicolegal

Malpractice Res Ipsa Loquitur, Admissibility of Evidence as to Indemnity Insurance—The defendant-physician operated on the plaintiff, removing a fibroid tumor and a diseased appendix. The operation was successful and the patient obtained the desired relief. At some time subsequent to the recovery of consciousness, however, a large blister was found on the chest of the plaintiff, for which injury she sued the defendant. The trial court gave judgment for the plaintiff, and the defendant appealed to the Supreme Court of Montana.

The defendant contended, among other things, that the complaint contained only general allegations of negligence whereas it should have set forth the specific acts or omissions on which recovery was sought. The plaintiff said the court sought to avail herself of the doctrine of *res ipsa loquitur* and in a case in which that doctrine is applicable general allegations of negligence are sufficient. The doctrine of *res ipsa loquitur* continued the court while not applicable to the ordinary malpractice case is applicable to the present case for the reasons given in *Brown v. Shorthidge* 98 Calif App 352 277 P 134.

This is not the ordinary case where the practitioner is sought to be charged with liability for alleged improper treatment of some bodily ailment or infirmity. He was employed to remove the adenoids from the plaintiff's throat and there is neither claim nor proof that he did not successfully remove them. His negligence if any was in failing to take due care to avoid injury to the undiseased parts in the vicinity of which the operation was performed and while it may be true that had the operation upon the adenoids been unsuccessful and disappointing no inference of negligence or want of skill would arise therefrom it does not follow that this rule applies with the same force to an injury done by him to sound and undiseased parts of the plaintiff's person which he was not called upon to treat and did not pretend to treat.

Where the rule is applicable, it operates to establish a prima facie case for the plaintiff which if unexplained, carries the question of negligence to the jury.

The evidence in this case established the fact of the burn but did not explain just how or when it was inflicted. Under the rule of *res ipsa loquitur* continued the court the circumstances proved by the plaintiff were such as to point by fair and reasonable inference to the conclusion that the defendant was guilty of negligence. They were sufficient to take the case out of the realm of conjecture and to support a finding by the jury that the defendant was guilty of negligence. The evidence offered by the defendant tended to rebut the inference arising from the prima facie case established by the plaintiff but such evidence was not so overwhelming as to cause the presumption of negligence to fade away in the face of contrary facts or point to freedom from negligence with such certainty as to preclude any other reasonable hypothesis.

The defendant vigorously urged that the counsel for the plaintiff was guilty of reversible misconduct in injecting into the case a statement that the defendant was insured. The injection of the insurance issue into damage actions has been repeatedly condemned said the court. The general rule on the subject is discussed in an annotation to the case of *Stehouwer v. Lewis* 74 A. L. R., 849, as follows:

The rule is almost universally recognized that in actions for personal injuries or death the fact that the defendant is protected by indemnity insurance against liability for damages cannot directly or indirectly be injected into the case by evidence argument or remarks so as to influence the jury and the violation thereof is ordinarily held to be reversible error.

The general rule however, is subject to the important exception that statements as to insurance protection of a defendant may properly be admitted as a part of a statement which may be fairly construed as an acknowledgment of a responsibility for the wrong charged against him. The present case does not come within the exception, so the general rule applies. In injecting the matter of insurance therefore the counsel for the plaintiff erred and thereby prejudiced the defendant's cause. The judgment of the trial court was reversed and the cause remanded for a new trial.—*Onault v. O'Rourke* (Mont) 33 P (2d) 332.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Hormones in Relation to Reproduction.—To explain the relation of the hormones to reproduction, Moore discusses (1) the double functional potentiality of the sex glands, (2) the control of the essential accessory reproductive organs the non-essential characteristics and to some extent the psychic behavior by the homologous sex hormone and the absence of an effect from the heterologous sex hormone (3) the threshold of effectiveness of hormones, (4) the lack of effect of gonad hormones on the gonads themselves (5) the absence in the gonads of the power of self regulation, and (6) the principle that hypophyseal activity is modified by the gonad hormones (there is a reciprocal interaction between the gonads and the pituitary). The author believes that sufficient detail has been presented to indicate that many of the phenomena of reproduction are interpretable on the basis of the working hypothesis presented. This type of explanation has been of service in his laboratory in suggesting lines of experimental attack on several problems. He anticipates, however, that many other factors will be found to enter into the mechanisms of control of the phenomena discussed and admits that several facts are difficult to fit into the scheme suggested. He states that with an increase of present knowledge and the evaluation of factual information there is little doubt that understanding of the mechanisms of control will advance. It is probable that other endocrine glands

will have to be placed in the chain of events as a necessary link, but until the interpretations are clear, working hypotheses will have a place.

Pregnancy and Heart Disease.—Fitzgerald reports on the management of pregnancy in 126 cases in which there was no reasonable doubt as to the presence of organic heart disease. Of the 126 cases, 107 presented mitral disease and sixty one of these showed evidence of stenosis. The patients were all examined at frequent intervals during their pregnancies. Whenever a patient was unable to do her ordinary activities without dyspnea or fatigue whenever she had difficulty in lying down without more than one pillow under her head and whenever she developed a cough even with no other symptoms, she was immediately hospitalized. If at routine examination the pulse was more than 100 when at rest or if any irregularity developed she was hospitalized even if symptoms were absent. To protect the patients from the development of such conditions they were required to spend two hours of each day at complete rest. Digitalis was never given during pregnancy while the patient was at home. In the hospital when the symptoms were of great importance the advice of the physician in charge of the heart clinic was requested. These patients were hospitalized for a few days before they went into labor when indicated. By this method of hospitalization at the first sign of significant evidence of myocardial stress the author was enabled to carry the entire group through pregnancy without alarming symptoms. Treatment during labor was simple. In labor as well as during pregnancy, no distinction was made between the various types of heart lesion other than as a matter of record. The routine sedative used was one-fourth grain (0.016 Gm.) of morphine and $\frac{1}{160}$ grain (0.0004 Gm.) of scopolamine hypodermically. This was given in primigravida as soon as the cervix was dilated 3 cm., and in multigravida as soon as labor had definitely begun. The dose was repeated after four hours if it seemed advisable. In the second stage if progress was rapid the normal process was not interfered with. If at any time after the cervix was completely dilated progress was slowed or there developed any symptoms of cardiac distress delivery was accomplished by forceps under ether. These patients when once in labor made satisfactory and frequently rapid progress. In the primigravida the longest labor was twenty-nine hours, the shortest labor was six hours and the average was ten hours and fifty minutes. The multiparas had an average labor of five hours and forty minutes, the extremes being three hours and ten minutes and eight hours and fifty minutes. Under this management 126 patients have delivered 189 babies. Two patients aborted spontaneously before five months. Three nonviable premature babies including one pair of twins, were born. Eleven patients went into labor prematurely, but after their babies had become viable. Two of these babies failed to survive. One full-term normally delivered infant developed pneumonia and died. No patient died during pregnancy or labor. One died six weeks post partum from an acute bacterial endocarditis, which developed after labor. One died nine months post partum at the age of 45. No patient was delivered by cesarean section, because of the heart condition.

Cigaret Smoking and the Fetal Heart Rate.—Sontag and Wallace made a study of the fetal heart rate, before and after maternal smoking, eighty-one times on five patients. The average fetal heart rate for five minutes before smoking was 144.0 ± 0.14 . The average fetal heart rate for the eighth to the twelfth minute after a cigaret was lighted and smoking begun was 149.0 ± 0.13 . The average increase in the rate was 5.0 ± 0.19 beats. Since the difference in rates before and after smoking is more than twenty-five times the probable error of the difference the effect of smoking is actual. Of the five patients, four showed an increase in the fetal heart rate after smoking while the fifth showed a decrease. The four showing increases were habitual smokers who inhaled the smoke. The patient showing a decrease had never smoked before, did not inhale, and expelled the smoke from her mouth as quickly as possible. There were occasional negative trials in each of the four patients showing an increase. These occurred for the most part at times when the fetal heart rate during the control period was above its average. The increase in the fetal heart

rate appears to be due to the passage of the toxic products of tobacco smoke into the fetal circulation, where they affect the fetal heart rate in the same way in which the adult heart rate is affected. Since the toxic effects of tobacco on young children and of nicotine contained in mother's milk on nurslings have been reported a careful study of the new born offspring of mothers who smoke heavily during pregnancy is indicated. Evidence of injurious effects of smoking during pregnancy may be overlooked.

Iodized Poppy-Seed Oil Injection and Air Insufflation in Sterility—Rabbiner points out that a review of the literature indicates that routine injections of iodized poppy-seed oil are not harmless and that as a diagnostic method it carries a morbidity and mortality even though small. The use of these injections in cases of sterility is unwise until a complete history, a careful bimanual examination, an endocrine survey, air insufflation tests, study of the vaginal chemistry, and investigation of cervical disorder and of the fertility of the male have been made. Operations on the tubes should be postponed for several months after the injections. In sterility cases in which one tube is occluded or both tubes show partial occlusion, as demonstrated by air insufflation the injections of the oil should be used cautiously since complete occlusion may result and thus defeat the primary objective. Air insufflation yields the desired information regarding the condition of the tubes, without harm and subsequent sequelae. This has been the author's experience in a large number of cases. The contention that the oil may remain in the peritoneal cavity for a year or more and result in serious pathologic changes has been verified by personal experience and the publications of others. Misinterpretation is not unlikely in the reading of salpingograms by the inexperienced; errors are few after trans uterine insufflation.

Subacute Lymphatic Leukemia—Stasney and Downey observed a case of lymphatic leukemia in which the biopsy of a lymph node from the earlier stage of the leukemic involvement revealed a marked hyperplasia of the reticulum. At the same time in the peripheral blood there were a number of large reticulo endothelial cells in addition to immature lymphocytes. In many instances these reticulo endothelial cells showed a nucleus with a rather dense chromatin structure resembling a nucleus of a lymphocyte. In a later stage at the second biopsy the medullary portion was packed with a dense mass of large immature lymphocytes, while the cortical region showed more or less well preserved germ centers. The subsequent disappearance of the large reticulo-endothelial cells from the peripheral blood was also noted. Therefore the first involvement of the leukemic process seems to begin with a diffuse proliferation of the reticulum. It was noted that the chromatin structure became more condensed. Numerous transitional forms from reticulo endothelial cells to large lymphocytes were found in the imprint preparations and in the peripheral blood from the earlier stages which later disappeared. In a later stage the medullary portion was entirely replaced by a dense mass of large cells with basophilic cytoplasm. It was only in the cortical region that a few more or less well preserved follicles were retained. Simultaneously in the peripheral blood there was a marked increase of immature lymphocytes. This indicates that in the lymphoid tissue the mesenchymal syncytium is rather uniformly distributed and that lymphocytopoiesis is

not restricted to the germinal centers or to preformed germ center cells. The evidence of extramedullary myelopoiesis in the medulla, as well as in germinal centers, the marked monocyte production in cases of leukemic reticulo-endotheliosis and finally the transformation of the mesenchymal syncytial cells into lymphocytes indicate the embryonic hematopoietic potency of the syncytial reticulum cells.

Hepato-Adrenal Necrosis with Intranuclear Inclusion Bodies—Hass witnessed intranuclear inclusion bodies in the parenchymal cells of the liver and adrenals of a 2 weeks old premature infant (seven months) in whom the chief pathologic changes were a widespread necrosis of the liver and focal cortical necrosis of the adrenals. He assumes that the unique lesions must have been produced by a filtrable virus.

Myocardial Lesions in Subacute Bacterial Endocarditis—Saphir examined the myocardium of thirty five hearts of patients dying from subacute bacterial endocarditis. Sections from various portions of both ventricles were embedded in paraffin and stained with hematoxylin-eosin. The Gram Weigert and the Van Gieson stains were also used. Frozen sections were often cut and stained with sudan III to demonstrate the presence of fat. In some instances serial sections were cut from a whole block and stained with hematoxylin-eosin. The prussian blue reaction was employed to determine the presence of iron containing pigment. Grossly the myocardium almost invariably was softer than normal, its cut surface was of a boiled appearance and the architecture was obscured. Just beneath the endocardium many minute yellowish streaks were often observed which occasionally were arranged in the form of tiger stripes. These were particularly evident in the papillary muscles of both ventricles. In some hearts the myocardium was traversed by grayish yellow and grayish red streaks and had a peculiar speckled appearance. Occasionally circumscribed minute yellow nodules or larger, soft yellow areas were encountered which were surrounded by hemorrhagic zones. Only in one case could an embolus be demonstrated grossly in the coronary artery. The aortic valve in this heart was almost completely destroyed and all three cusps were practically replaced by large soft grayish red vegetations. Mycotic aneurysms were found in the sinus of Valsalva corresponding to the left and posterior aortic cusps. The distal portion of the circumflex branch of the coronary artery at the point of origin of the ramus marginis obtusus was occluded by an embolus which was reddish gray, soft and similar in every respect to the vegetations on the aortic valve. In six hearts petechial hemorrhages were encountered. More commonly the subendocardial layer was involved but occasionally the myocardium in an area at a distance from the endocardium was affected.

Visualization of Suprasellar Tumors by Encephalography.—Hamby and Gardner discuss the encephalographic characteristics in nine cases of tumors of the suprasellar region: four craniopharyngiomas, two suprasellar meningiomas, two gliomas of the optic chiasm and one arachnoid cyst. The characteristic observations in these tumors are obliteration of the cisterna chiasmatis, diminution of the frontal cerebral sub-arachnoid spaces and more or less encroachment on the ventricular system. The different types of tumor appear to present some differential features. The craniopharyngiomas showed in addition to the general features an anterior-inferior filling defect in the third ventricle and more or less obstruction of the foramina of Monro with resulting hydrocephalus. The meningiomas showed in addition to the general features, outlining of the superior border of the tumor with less compression of the third ventricle. Filling defects were noted in the floors of the anterior horns of the lateral ventricles. The gliomas of the optic chiasm await further observations for the establishment of a clear conception of their characteristics. The increased size of the infundibulochiasmal shadow in a normal cisterna chiasmatis, in a patient having a syndrome indicative of chiasmal damage, seems suggestive of a chiasmal glioma. The outline of a normal chiasmal cistern on the encephalogram excludes the possibility of a surgical lesion in this region.

Benign Stricture of Stomach and Esophagus.—Sagel cites two cases that show strictures of both the stomach and the esophagus due to ingestion of alkalis. While benign stricture of the stomach and esophagus is a relatively rare condition, it should be thought of when esophageal and gastric lesions do not show changes characteristic of other diseases. A concomitant lesion in the esophagus and the stomach is suggestive of benign stricture. A history of the swallowing of corrosive material is of course of prime importance in establishing the diagnosis. The author enumerates observations which he believes will aid in the diagnosis and differentiation of this condition from other esophageal and gastric lesions.

Treatment of Carcinoma of Uterine Fundus with Radium.—The basic principle of the present technic of Bowing and Fricke for the treatment of carcinoma of the uterine fundus consists of intensive application by the broken dose method and the use of simple applicators which are gamma-ray tubes containing 50 millicuries of radon, as the unit of treatment. This permits wide choice so that treatment can be individualized. As the lesion cannot be accurately outlined their purpose is adequate homogeneous irradiation of the uterine canal, including the cervix when involved, supported by vaginal irradiation. Radium element needles are employed in cases of metastasis

to the vaginal wall, and surface packs are used if the inguinal lymph nodes are involved. Treatments with x-rays are given following the course of radium treatments, especially in inoperable cases and in those in which the lesions are of a high grade of malignancy. The whole problem is mainly surgical, although when operation is contraindicated many lesions may be satisfactorily arrested or apparently "cured" by careful irradiation. In inoperable conditions, palliation is usually secured by limited treatments.

Study of Effect of Artificial Fever in Hopeless Tumor Cases.—Warren states that there is *in vitro* (and some *in vivo*) experimental evidence suggesting a definite "thermal death time" for transplantable animal tumors at high febrile temperatures. There is a distribution of heat by the circulating blood in the febrile state so that the internal organs and tumors in animals, and presumably in man, reach and can be maintained at any predetermined temperature level. This is usually nearly equal to the rectal temperature. On this basis, thirty-two hopeless advanced human cases of different types of malignant disease were treated by generalized fever therapy and a combination of fever therapy at 41.5 C (106.7 F) and high voltage roentgen therapy. In cases treated previously by high voltage roentgen therapy and in untreated cases, fever therapy seems to have a definite destructive effect on the tumor cells. The amount of destruction and its duration varies from case to case. Further work on this aspect of the treatment of malignant disease seems to be warranted in the hope of obtaining an additional aid in the treatment of this malady. No results approaching cure have yet been obtained by this procedure. In all cases but three, after the fever treatment there was immediate improvement in the general condition, lasting various periods of time (from one to six months), with gain in weight and strength and with shrinkage of tumor masses of various amounts and duration. Evidence of return of growth of the tumor process in all patients occurred at various intervals and rates. It was the clinical opinion of those concerned that because of the rapid growth of the tumors and the condition of the patient the probable length of life was restricted (from one to three months).

Leukocytes in Syphilis in Rabbits.—Lowenstein noticed an increase in the number of phagocytic mononuclear cells in early acute experimental syphilis in the rabbit. Qualitatively these cells showed evidence of increased physiologic and phagocytic activity. There was also a decrease in the number of lymphocytes. The degree of increase in the large phagocytic mononuclear cells paralleled the degree of activity at the site of the testicular lesions. No significant changes were observed in the total number of leukocytes or in the other leukocytic elements of the blood, while gross testicular lesions were present.

Comparison of Cerebrospinal Fluid from Cisternal and Lumbar Punctures in Syphilis.—From the comparative study of cisternal and lumbar fluids in syphilis Moskvin and his associates conclude that 1. While one is performing the Wassermann test it is necessary to use 1 cc. of the fluid as the initial maximal quantity, carrying out the test quantitatively with the amounts 1.05 and 0.1 cc. 2. The employment of various methods of extract dilution helps to carry out a

more exact estimation of the Wassermann test variations in the cisternal and spinal portions. The Wassermann reaction does not differ greatly in either portion, but the variance is usually observed within the limits of two-plus. The positiveness of the colloidal and protein tests and lymphocytosis is more marked in the lumbar portion. The difference is the least pronounced in the benzoin test. 3 In the cerebral forms of syphilis the cisternal fluid does not differ significantly from that of the lumbar region. 4 In the cerebrospinal fluid diagnosis of syphilis the principal part is the examination of the lumbar fluid. Yet the examination of cisternal fluid is an extremely valuable adjunct to it; it is necessary (1) for the study of pathologic dynamics of the spinal fluid when frequent examinations of the lumbar fluid are impossible owing to meningism, (2) in cases in which the lumbar puncture is contraindicated and (3) in cases in which the spinal fluid cannot be obtained by lumbar puncture.

Draining the Abdominal Cavity in Peritonitis.—Breitman believes that the removal of exudate may be achieved in a sufficient measure, avoiding the dangers and complications connected with drainage, in the following manner. After the usual manipulations within the abdominal cavity in cases of acute peritonitis, the gastrocolic omentum, if it has not been destroyed by some inflammatory process, is spread over the intestinal loops, the drainage tube is wrapped in gauze and laid on the omentum, and the abdominal wall is sutured by layers with the exception of the lower end of the wound which serves as an outlet for the drainage tube. A sufficiently thick bandage is applied so that it will absorb the exudate discharged through the drainage tube. On the next day the wet top layers of the bandage are changed. Applied in this manner the drainage tube is not located amid the intestinal loops, being isolated from the latter by the omentum. Consequently it is hoped that there will be neither adhesions of the intestinal loops nor injury to the intestinal walls due to the action of the tube. The author is of the opinion that under this arrangement a sufficient discharge of exudate is possible because the bandage quickly becomes wet during the first hours after the operation, so that it becomes necessary to reinforce it. On the next day the upper layers of the bandage, which are changed, are saturated with exudate. The author employed the foregoing procedure in six cases of general peritonitis of different origin: one of peritonitis caused by perforation of a duodenal ulcer, two of appendicitis with peritonitis, two of peritonitis caused by volvulus of the cecum, and one of peritonitis caused by volvulus of the sigmoid flexure. The drainage tubes were removed on the fifth to the seventh day. Five of the patients recovered and one died on the sixth day with symptoms of postoperative pneumonia. The author does not consider the method a panacea for the treatment of peritonitis but the method is the working hypothesis of a practical surgeon, which deserves a certain amount of attention and should be verified on a larger amount of material.

Submucous Lipomas of Intestinal Tract.—In 5,754 consecutive necropsies performed at the Cook County Hospital, Kirshbaum states that nine cases of lipoma of the gastrointestinal tract were found. While in seven cases the lipoma was merely an incidental observation and measured from 1 to 3 cm in diameter, in two of the cases the tumor proved to be of grave significance. In one of these two cases the lipoma became sequestered, mobilized and lodged in the lower ileum, occluding the lumen. The second tumor induced an intussusception of the lower 8 inches of the ileum into the cecum. Both cases resulted in death, and necropsy disclosed a diffuse peritonitis. Lipomas were the second most frequent type of benign tumors of the gastrointestinal tract encountered in the 5,754 necropsies. Of the nine cases reported, eight were of the submucous type and one was subserous. The diagnosis of submucous lipoma of the intestinal tract is almost never made during life.

Treatment of Recurrent Incisional Hernia.—Rothschild submits a procedure for recurrent incisional hernial flaps of the anterior sheath of the rectus. The first step consists of an adequate exposure of the sac of the hernia and the anterior sheaths of the right and left rectus muscles. The sac should be opened in all cases in which the contents cannot be reduced, which permits the severance of adhesions of the omentum to the sac and the exploring of the upper part of the abdomen. The sac is then excised and its edges are sutured. When the contents of the sac are reducible, the sac may be reduced in size by the inversion method of Haynes. The second step consists in the clearing of the anterior sheath of the rectus of all adipose tissue. The longitudinal and transverse diameters of the hernial orifice are measured. Markings are made on the anterior sheaths of the rectus muscles to designate the length of the flaps desired. Markings are also made to designate the width of each flap, so that when the flaps are sutured together they will cover the hernial orifice without undue tension. The flaps are raised and lunged along their medial border. They are then sutured by a continuous stitch. The upper and lower edges are sutured by interrupted stitches to the remaining portion of the anterior sheath of the rectus. Redundant skin is removed; stab wounds are made at the lowest level and drains are inserted at these points. The wound is then closed. When the hernia is the result of an upper right rectus incision the flap of the left rectus sheath will necessarily be larger than the flap obtained from the right side, while in hernia occurring in the midline the flaps will be of the same size. Adequate drainage should be established because of the extensive dissection of the skin and subcutaneous fat. Abdominal distention should be avoided. To lessen the distention or to avoid it in the upper portion of the abdominal cavity, the author uses the Jutte tube immediately after the operation. It remains in place four or five days whether distention is present or not. These patients are kept flat on their backs with but one pillow to elevate their heads for a period of four weeks.

Structure of Secondary Nodule of Tonsil.—Novak found that whereas the reticular fibers branch, anastomose and ramify with no regularity of pattern throughout the tonsil with the exception of those areas in the immediate vicinity of the secondary nodule here they assume a pattern that is constant and regular. The fibers are fairly thick and are arranged more

or less parallel to one another in two or three rows. In sections stained with hematoxylin and eosin it is readily seen that the small dark staining lymphocytes which are packed in sharply parallel rows at the periphery of the nodule correspond in their arrangement to the concentric and parallel arrangement of the supporting fibers in this part. This arrangement does not obtain round the entire periphery in some of the nodules. Some of them show a dispersion of the fibers at one pole. It is at this point that one frequently observes minute blood vessels in cross section just outside the nodule. In one section a small vessel cut tangentially was seen to be entering the interior of the nodule. These vessels are difficult to demonstrate except by silver impregnation. The arrangement of the reticular framework within the nodule differs from that of the rest of the tonsil in that the fibers do not seem to interlace as much as they do elsewhere. Moreover the fibers are thin and even in serial sections are difficult to trace for any distance. The arrangement is far looser and there are wide spaces that in counterstained preparations are seen to be packed with various cells. The cellular content of the nodule is shown by differential staining consists of lymphocytes of various size and maturity. There are many reticular cells the nuclei of which alone stand out definitely as the cytoplasm has no limiting cell boundary but forms part of a true syncytium. Mast cells and an occasional plasma cell are found.

Hypertrophy of Remaining Kidney After Nephrectomy.—The experiments of Bollman and Mann indicated that hypertrophy of the remaining kidney after nephrectomy is greatly increased by accumulation of urinary products in the blood following transplantation of the ureter so that the urine drains into the duodenum. The kidney increased in weight from 60 to 100 per cent within nine days. The glomerular tufts are enlarged, but most of the increase appears to be due to swelling and multiplication of the cells of the tubules in which there is some evidence of early degeneration. Creatinine apparently does not accumulate in the blood under these conditions until degeneration of the kidney appears.

Experimental Siderosis.—Menkin and Talmadge state that whereas repeated intravenous injections of a 0.25 per cent solution of ferric chloride in distilled water are followed by extensive siderosis there is no appreciable change in the number of red blood cells, the percentage of hemoglobin or the reticulocyte count. Since this solution of ferric chloride is hypotonic its injection into the circulation induces a certain amount of hemolysis. However the tanning action evidently plays an insignificant part in the formation of iron-containing pigment for when a nonhemolytic, isotonic solution of ferric chloride is substituted for the hypotonic one the same type of deposition of cytosiderin occurs. Furthermore when a hypotonic saline solution is repeatedly injected intravenously iron-containing pigment fails to be deposited. These experiments furnish evidence that iron-containing pigment (indistinguishable from hemosiderin) need not be derived solely through the action of phagocytes on the products of the degradation of hemoglobin but may arise also as a result of the intracellular digestion of available iron containing material exogenous as well as endogenous.

Childhood Myxedema Emphasizing Bone Age Studies

—Canelo and Lissner report two cases of childhood myxedema—one a girl of 12, the other a woman of 34. The girl showed an ossification age of from 6 months to 1 year. In the woman the epiphyses were still ununited and her bone age was estimated at 10 years. The diagnosis of childhood myxedema was clinically obvious in both patients, but roentgenographic studies of bone age were an important item in gauging the severity of thyroid deficiency. A basal metabolism test could not possibly have been performed in the stupid child of 12. Bone age studies were easily obtained with accuracy and without discomfort. Other ailments endocrine and nonendocrine, influencing ossification are referred to. Periodic bone age determinations constitute a simple and helpful adjunct in judging the efficacy of thyroid therapy in childhood myxedema.

Nature of Estrogenic Substance in Male Urine and Bull Testicle.—Dorfman and his associates compared the uterine hypertrophy and vaginal introitus responses of equivalent rat unit dosages of theelin, theelol and estrogenic substance from male urine, made at estrogenic levels ranging from 0.01 to 0.3 rat unit. Their method involved the daily administration of the active material in olive oil to female albino rats 25 days of age for five days, and observing the uterus and vagina on the sixth day. Litter mates were used throughout the comparative studies and 161 animals were used for the comparative studies. The quantitative data lead to the following conclusions: 1. There is a distinct difference between theelin and theelol in their respective abilities to cause hypertrophy of the uterus and cause vaginal introitus. On an estrus-rat unit basis, theelol is more effective in causing vaginal introitus as originally demonstrated by Curtis and Doisy, whereas theelin produces an enormously greater uterine hypertrophy. 2. The estrogenic substance in the total benzene extract from normal male urine resembles neither theelin nor theelol in causing either vaginal introitus or uterine hypertrophy. 3. The estrogenic substance in the alkali soluble fraction of the total benzene extract is biologically identical with theelin. It is not comparable to theelol in causing either vaginal introitus or uterine hypertrophy. 4. The evidence presented points to

the presence of a substance in the alkali-insoluble fraction of the total extract which, when administered with theelin, enhances the action on both the vagina and the uterus. This substance is neither theelin nor theelol.

Attempts to Reduce Symptoms of Diabetes by Irradiation of Hypophysis—The experiments of Selle and his co-workers show that of seven diabetic (depancreatized) dogs the fasting blood sugar was not reduced in five after irradiation of the hypophyses by high dosage. In three animals the blood sugar was considerably higher after irradiation. The response to ingested dextrose was always typical of severe diabetes. There was no increased sensitivity to insulin and the insulin dosage necessary to prevent glycosuria on a well controlled diet could not be reduced. No indication then was found that massive irradiation of the hypophysis with x-rays under the conditions stated reduces the severity of the symptoms of experimental diabetes.

Erythroblastic Anemia—Strong points out that in erythroblastic anemia several features seem to stand out in every case reported since Cooley's first description. The children usually resemble the Mongolian race. There is a peculiar yellow, muddy discoloration of the skin with a thickening of the cranial bones and the malar eminences. This thickening is more pronounced as the disease progresses. The changes in the bones are promptly recognized as being peculiar to this form of anemia when roentgenograms are made. The skull shows a marked thickening and a peculiar 'hilo' resembling the growth of hair. A peculiar mottled or 'mosaic' appearance of the bones of the hands and pelvis is observed. There is a decreased density, amounting almost to transparency of the fibula and tibia. The explanation that has been offered for these changes in the bones is that they are the result of the reaction of the marrow to prolonged overstimulation as a consequence of a chronic hemolysis beginning before the cortex is too firm to permit the overgrowth of marrow. In the earlier stages and in less severe cases the porous appearance in the roentgenograms seems to represent marrow hyperplasia while in the terminal stages the pronounced striation indicates replacement of exhausted marrow but new bone has been found at necropsies. The bone change is not primary. Most of the cases seen have been either in Italians or in children of parents from the Mediterranean countries. Evidence of bone marrow stimulation characterized by the great number of immature forms, a constant leukocytosis and the absence of increased fragility, seem to be the principal features of the blood picture. The hemoglobin in every case has usually been round 30 to 40. The red cells are reduced considerably. There is usually a leukocytosis of 20,000 or more, but the differential count is not especially remarkable. The cells vary greatly in size and shape, and there are usually a considerable poikilocytosis and anisocytosis. There is a marked and early bone marrow irritation which is reflected in the production of the increased number of leukocytes. As the development of the marked bone hyperplasia increases these numbers may run to a high figure. In erythroblastic anemia, fragility of the erythrocytes to hypotonic salt solutions is conspicuous by its absence. It is for this reason that this particular form of anemia is not considered to be a true hemolytic jaundice, which invariably shows an increase in fragility of erythrocytes to salt solutions. In no other disease of the blood is there a greater number of erythroblasts than is seen in erythroblastic anemia. Moreover after a splenectomy their number increases remarkably but so far as available results are concerned there seems to be little

definite improvement in the patient. Hemolysis and jaundice may be temporarily lessened, but the disease process continues. The benefit to the patient lies mostly in the removal of the drag of the heavy spleen.

Neurotologic Studies in Epilepsy—Langdon states that it is evident that a large proportion of active idiopathic epileptic patients show some departure from the responses obtaining in normal persons. There is no one response, however, that is constantly lacking in all the cases. One cannot help being impressed with the large number that show absent or subnormal constitutional responses in that after this more or less violent ear stimulation they are not disturbed showing no pallor, sweat or nausea whatever. Quite similar responses are encountered in cerebrospinal syphilis and arteriosclerosis of the cerebral vessels. Both these conditions give subnormal responses, but the absence of the constitutional responses is not so marked as in epilepsy. Modern investigators no longer consider epilepsy a clinical entity but are inclined to speak of it as a symptom complex or syndrome. The pathogenesis of this disease has been the subject of a great deal of speculation and has not escaped even the most extravagant fancies. The cause has been ascribed to pathologic conditions ranging all the way from congenital cerebral anomalies to gastro intestinal auto-intoxication. The phenomena accompanying the aura have long interested the otolaryngologist. It is generally accepted that the vestibular pathways go through the brain stem and are intimately associated with the basal ganglions, and that a failure to get a normal response in the epileptic patient would seem to indicate at least that some of the pathologic changes are located in the region of the basal ganglions. The author offers this only as a suggestive link in the chain of evidence tending to show that epilepsy is not entirely a cortical disease, as once thought but that at least a phase of the seizure does arise from the lower centers.

Chronic Duodenal Ulcer Without Stenosis—Farquharson points out that the early acute ulcer and the chronic ulcer of short standing are essentially the province of the physician and, with energetic medical treatment can be cured in the vast majority of cases. At the other end of the scale the late complication of cicatricial stenosis renders medical treatment unavailing. Gastroenterostomy has shown undisputedly excellent results in this condition. However, the vast majority of cases of duodenal ulcer do not permit of such simple division. It is comparatively rare for either the medical or the surgical specialist to see an ulcer patient in the early stages of the condition. Unless acute emergencies such as severe hemorrhage or perforation, suddenly establish the diagnosis the condition is usually overlooked or treated in the early stages as simple dyspepsia. Energetic medical treatment is seldom employed before the diagnosis is established definitely. The modern necessity of roentgenologic and biochemical facilities as aids to diagnosis, means that the ulcer patient rarely receives adequate medical treatment until he is referred to the hospital or to the specialist. Statistics regarding the duration of symptoms prior to hospitalization indicate that at least 70 per cent of patients have symptoms for four or more years before the diagnosis is established and adequate medical treatment commenced.

Some Factors in Causation of Rheumatism B S Nisse—p 71
Paragonimus Hemoptysis Case R A Bennett—p 76

Diagnostic Significance and Treatment of Ascites—Hutchison gives the probable causes of ascites as being a part of a general dropsy (cardiac or renal) the result of portal obstruction, obstruction of the inferior vena cava high up inflammatory effusion, abdominal tuberculosis (chiefly in children), chronic (nontuberculous) peritonitis and peritoneal irritation, though it is difficult to draw a sharp line between irritation and inflammation. As ascites is a sign and not a disease, it is not worth while trying to get rid of it unless it is causing great inconvenience. Drugs are not of much help. Purgatives have to be used cautiously. Ordinary diuretics are useless, but salyrgan, given intravenously or muscularly (from 0.5 to 1 cc.), is sometimes of great value especially if used

with ammonium chloride (120 grains, or 8 Gm, daily). Apart from meeting any indications furnished by the underlying disease, it is reasonable to restrict fluids as much as the patient can bear and to make the diet as free from salt as possible. In abdominal tuberculosis, evacuation by laparotomy is best. In women incision is sometimes to be preferred. In most cases of ascites, if the fluid should be evacuated, tapping is the method of choice. It is best to make the puncture in the flank and to use a trocar with a tube of moderate caliber. The fluid should be evacuated in any case in which its presence is causing serious inconvenience. Operations designed to promote absorption of the fluid by establishing an anastomosis between the portal and the general circulation have practically been given up. They were founded on the assumption that ascites is due to portal obstruction, which is not true for most cases.

Treatment of Enlarged Spleens with Injections of Milk A P Jana—p 687

Treatment of Enlarged Spleens with Injections of Milk—Jana treated 319 cases of enlarged spleen by injecting milk free from fat. Eighty of the patients have been discharged as cured and 146 received only one injection and did not return. The outcome in 173 cases was noted to some extent of these 173 cases ninety-eight presented soft spleens, fifty-four hard spleens and in twenty-one cases the consistency of the organ had not been noted. Of the eighty cured cases there were fifty-six soft spleens, eighteen hard spleens and in six cases the consistency of the spleen had not been noted. Of the hard spleens one was of a duration of ten years and was cured with three injections one of six years was cured with fourteen injections one was cured with five injections, two were of a duration of four years and were cured with four injections. The duration of the others was less than one year. Among the improved cases there must be many cured, as on inquiry three cases were found to be cured after the first injection. These were cases of recent origin with small sized spleens. As a result of his experience the author concludes that enlargement of the spleen is reduced by intramuscular injection of milk free from fat. Milk injection is effective in enlargement of the spleen due to malaria. In enlargement of the spleen due to kala-azar it has little effect if any. In one case four injections were given regularly but no effect was observed and the patient was subsequently treated and cured with dimethylamine *p*-aminophenyl stibimate. Soft spleens are easily reduced in size with this treatment. The progress of improvement is slow in hard spleens. After the completion of one course of five injections a second or third course is sometimes required a gap of one month being given between courses. The longer the duration of the enlarged spleen, the more the number of injections and the longer the time required for its cure.

Diagnosis and Treatment of Abscess of the Brain—

In their discussion on abscess of the brain, Cairns and Donald describe methods of operation and then analyze their material, especially the failures. They discuss the thick-walled chronic abscess, the acute and early chronic abscess, drainage by the closed method and open method, after-treatment of the acute and chronic abscess, postoperative complications and errors in diagnosis and treatment, presenting illustrative cases in each instance. They believe that the many difficulties of diagnosis will be overcome by careful history taking and neurologic examination in the light of an accurate knowledge of the life history of brain abscess. If every patient who has severe headache after ear trouble or mastoid operation should be put through the mill of such an investigation, the bad results of today would be improved. They especially stress the importance of examining the visual fields. It is that part of the examination more than any other which cannot be done when the patient becomes lethargic and, for want of which, localization of the abscess in the stupefied patient may be so baffling. When intracranial complications are suspected, neurologic investigation should take precedence over mastoidectomy, since it will tell more about what is happening inside the dura than can be learned from looking at a small area of dura exposed in the region of the mastoid. Lumbar puncture should be done, but only 1 cc. of fluid should be withdrawn. Diagnostic exploration as they describe it is, they believe, important in certain cases. With each case of abscess there is need to form some estimate of when the abscess began and what stage it has reached, for this is the only way in which to gauge the right moment for intervention. This can be done only by careful study of the history of illness.

Diagnosis of Vitamin C Subnutrition by Urinalysis—

Harris and Rav observed that infants suffering from manifest scurvy or with a history of vitamin C underfeeding excrete less vitamin C in their urine (measured chemically) than do well nourished infants of the same age tested under the same conditions (on controlled diets low in vitamin C). The difference can be made more strikingly manifest by the administration of a large test dose of vitamin C—a marked peak results in the curve of the urinary excretion for the normal infants, but not for the "unsaturated" scorbutic or semiscorbutic infants. After cure the scorbutic infant behaves like a normal infant both in his output of vitamin C on ordinary diets (or controlled diets free from vitamin C) and in his response after the test dose. Observations on adults show that a low urinary output and a low response to test doses go parallel with a history of vitamin C underfeeding and with a state of vitamin C subnutrition as indicated by a lowered capillary resistance. The authors describe a technique that is being used to estimate the prevalence of hypovitaminosis C among certain sections of the community. The rarity of scurvy in breast-fed infants is explained by the

finding that human milk contains from three to four times the amount of vitamin C found in cow's milk, part of the latter is also lost generally (1) by pasteurization, (2) during standing, (3) by further heating and (4) by dilution.

Monocytic Leukemia—Whitby and Christie present a case of monocytic leukemia the clinical features of which show that it is not necessarily rapidly fatal, even when accompanied by acute symptoms such as fever, severe anemia and necrotic mouth lesions. There were two remissions—a feature unusual in other acute leukemias. The anemia in the first two attacks was much more severe than would have appeared probable when estimating the acuteness of the leukemic process by the number of primitive cells. The authors were impressed by the distribution of the necrotic lesions in the mouth, which appeared to select the alimentary mucosa rather than the respiratory part of the pharynx. Ulceration failed to spread on to the tonsil or into the nose. Terminal hepatic enlargement was coincident with the appearance of a frankly leukemic blood picture. This enlargement was not apparently due to heart failure and was unaccompanied by enlargement of the spleen and lymph nodes. Save for the terminal phases there was a definite granulopenia, and pentnucleotide was administered for this during the first attack. Violent reaction to the preparation prohibited its further use. The case, as judged by histologic sections, appeared to present a partial myeloid termination. The blood during the last few days of life contained a number of myeloblasts. The predominant cell throughout was an unmistakable monocyte. Histologic sections showed no evidence of proliferation of the reticulum cells of the spleen or of desquamation of newly formed histiocytes into the blood.

Clinical Observation of Beriberi Complicated During Pregnancy and Puerperium A Fujita—p 461

Effect of Vitamin B on Female Genital Organs—Ueno observed that in the deficiency disease of vitamin B the conceptive ability is depressed and some animals finally fall into sterility. But before the deficiency of the vitamin becomes intense, conception is possible, though various abnormal processes take place during the course of pregnancy, parturition and puerperium, for instance, anomalous hemorrhage of the pregnant uterus, intra-uterine absorption of fetuses, early interruption of pregnancy, weakened power of expulsion, and disturbance in the uterine involution. During the attack of the disease, the development of the fetuses is markedly hindered. In extreme cases some fetuses have been absorbed or macerated in the uterus and others have been delivered in stillbirth. Even if born alive, they are generally structurally weak and small in body length and among the fetuses born from the same mothers some variance was revealed in their body weight and length.

Allergic Factor in Colitis—Moynan discusses food allergy and bacterial allergy in colitis. He examined personally fifty patients having mucous or catarrhal colitis in whom bacterial sensitization was found. The colon bacillus was found in 84 per cent, enterococci in 42 per cent. Bacterium organism in 40 per cent and fecal, paracolon bacilli, streptococci and other organisms less frequently. Eleven patients with severe ulcerous colitis were also studied. In eight of these Bacterium diplo-streptococcus was the only organism found. Sensitivity of the patients was tested for each of the germs found with cultures killed by heat and injected intradermally. The reaction was read after one half hour, twenty four and forty eight hours. It was considered positive only when positive after one half hour and negative after twenty four hours. In some cases a focal and general reaction was observed as well as a local one. Control tests were also performed on some normal persons. Sensitivity was recorded for colon bacilli in 48 per cent for enterococci in 24 per cent, for paracolon bacilli in 16 and for others less frequently. In no case was there sensitivity to one organism alone. Desensitization by means of vaccine containing the indicated organisms was usually successful except in serious ulcerative colitis. Here the number of true positive reactions was less. In no case did the author observe exacerbation of symptoms from vaccine therapy. The results in this type of colitis were better than those obtained with any other form of therapy.

*Primary Necrotic Angina A. Stroc and D. Hortopan—p. 182

Hydatid Echo Sign—Lian and Odinet cite three cases in which the sound elicited by percussion and auscultation over a hydatid cyst enabled a diagnosis to be made in the absence of a hydatid murmur. This so-called echo sign is thus frequently useful.

Primary Necrotic Angina—Stroc and Hortopan have previously reported on the frequent complication of scarlet fever in Bucarest with necrotic angina (Henoch's angina). They conclude from this further study that the necrotic angina of Henoch constitutes a definite disease which appears most commonly as a complication of scarlet fever. More rarely it may complicate diphtheria or may appear as an autonomous and primary disorder. It is an infection and can be contagious and give rise to small epidemics. Anaerobic organisms, Bacillus perfringens and more rarely other organisms seem to play a preponderant if not exclusive part in its causation. The injection of polyvalent antigangrenous serum constitutes the only efficacious treatment that they have found and should be given in all cases.

Treatment of Cystic Formations—Lenggenhager points out that, if a cyst is emptied by puncture, it generally refills again, irrespective of its type, whether it is lined with epithelium or endothelium or whether it is a cavity that has developed by the disintegration of tissues. Newly developed pseudocysts are about the only exceptions to this rule since they may disappear following a single puncture (for instance hematomas

that are at the point of transformation into seromas). The cause of the prompt refilling of cysts lies in the great secretory power of the cystic endothelium or pseudo-endothelium and in the type of secretion. To be sure, the secretion contains protein but not all the factors necessary for spontaneous coagulation. Since the agglutinations in the peritoneal cavity are caused by fibrinous exudation the author reasoned that it ought to be possible to stimulate the cystic wall to fibrinous exudation. He obtained this result by the injection of saturated solution of sodium chloride. Such an injection is followed by the secretion of a fluid with a high protein content. The treatment is done in the following manner. The cyst is emptied by puncture and, if necessary (in case of new pseudocysts and hydroceles) a 0.1 per cent solution of nupercaine sufficient to fill one fourth or one third of the volume of the cyst is introduced for from one to two minutes. The anesthetic is removed and the cyst is filled with sterile saturated solution of sodium chloride. Depending on the thickness of the cystic wall the solution remains in the cyst for from two to three minutes. Then the fluid is removed, the cyst is irrigated with physiological solution of sodium chloride or with distilled water and a compressing bandage is applied. The latter is removed after eight hours and if at this time an exudate is still present the cyst is left alone for ten or fourteen days. If it still persists after that period, a second injection is made. However, in the majority of cases this is not necessary. The author employed this treatment in ten cases of chronic bursitis (elbow, knee), in traumatic hematomas, in one serous cyst of the auricle of the ear, in twelve ganglions, in two hydroceles and in two struma cysts. The treatment proved most effective in bursitis and in traumatic pseudocysts. In the ganglions the results were so favorable. Isolated results were obtained in cases of hydroceles and of struma cysts, but the author does not recommend the treatment for struma cysts in general.

Injections of Maternal Blood in Grave Vomiting of Infants—Sujoy reports satisfactory results from intramuscular injections of blood from the mother in the treatment of grave vomiting of infants. The injections are given in the gluteal region twice a week in a dose of 20 cc. of blood each. In all cases of the author the vomiting was controlled at the first injection in four cases, at the third injection in one case, at the fifth injection in four cases and at the sixth injection in one case. No accident occurred. Only in one case was blood taken from the father. None of the patients of the author had pyloric hypertrophy. The treatment seemed to be indicated even in cases of pyloric hypertrophy, having in mind the frequency of doubtful cases, the satisfactory results obtained by the medical treatment alone as reported in the literature and the seriousness of the surgical intervention in that condition. The pathogenesis of grave vomiting of infants is explained by the author as caused by a vagosympathetic disequilibrium, a vagal predominance of toxic origin that greatly improves or even disappears by the complicated and eutrophic action of maternal blood on the organism of the infant.

*Localized Inflammation of Cecum and Its Treatment H. Pich—p. 88

Treatment of Appendiceal Peritonitis—Reschke draws attention to the increasing mortality of acute appendicitis in type of case designated by Richardson as arriving at the hospital too late for an early operation and too early for a

operation is responsible for the increase. The author does not accept the rule not to operate after the lapse of forty-eight hours, since the inflammatory process may still be limited to the appendix. On the other hand there may exist a tender but well encapsulated infiltrate, which may go on to absorption or to abscess formation. The third possibility is that of circumscribed or spreading peritonitis. The author is of the opinion that not only the encapsulated abscess but the spreading peritonitis as well should be treated on a conservative plan and no longer submitted to an operative intervention. To prove the point he compares his results with those of Martens, his predecessor at the Greifswald clinic. The latter operated in the acute cases in all stages, making an exception for the encapsulated abscess only. Martens' total mortality in acute appendicitis was 79 per cent, while Reschke's was 35 per cent. The comparison of their cases in which early operation was performed shows, however, slight difference in mortality: 12 per cent in Martens' series and 11 per cent in the author's. The difference in the total mortality cannot therefore be ascribed to a difference in the operative technique. In the author's opinion it is due to the difference in the method of treatment of the late cases. Martens treated them radically, whereas the author proceeded conservatively, operating only when an abscess had formed and even then limiting himself to an incision from above or below. Of fifty-two late cases complicated by peritonitis, in which operation was performed by Martens, twenty-seven, or 52 per cent, of the patients died. In a series of similar cases treated conservatively by the author three patients out of eighteen died, a mortality of 16 per cent. The author concludes that when the opportunity for the early operation has been missed, better results will be achieved by waiting rather than intervening.

Problem of Myeloma—Mathias states that the appearance of Bence-Jones albumose in the urine of patients with myeloma though highly characteristic is not essential. It is found with the greatest frequency in cases with wide bony dissemination of the tumor. Classification of the tumor on a histogenetic basis does not appear to have much value in the case of myeloma. The designation erythroblastoma, lymphoblastoma or plasmacytoma, because of the preponderance respectively of immature erythrocytes, lymphocytes or plasma cells, throws no light on the essential nature of the tumor. The differentiating histologic feature of myeloma is that it is made up of all the immature elements of the bone marrow. The occurrence in myeloma of double refractory crystals, either as needles or as rhombic prisms, was described by Abrikosov. Because similar crystals could be obtained from the Bence-Jones albumose Abrikosov believed that myeloma was the expression of a variable structural reaction to a disturbed intermediary metabolism rather than a primary disease of the bone marrow. Local manifestations of myeloma are those of absorption of the bone with a tendency to fractures. Involvement of a vertebral body not infrequently causes compression of the cord. The most striking general manifestation is the progressive anemia and, next to it, the appearance of Bence-Jones albumose in the urine. The generally accepted idea that myeloma is a systemic disease has been recently challenged by the description of cases presenting a purely localized tumor. The author reports a case of his own and cites others reported by Geschickter, Crile and Bloodgood. In the author's case a tumor, which on histologic examination proved to be a typical myeloma of the plasmacytoma variety, was removed from the scalp of a man aged 65. Careful examination failed to reveal the presence of metastases in the skeleton. Reexamination eighteen months later likewise failed to show the presence of tumors. There was no anemia and no Bence-Jones albumose in the urine. The author concludes that, besides the generalized form of myeloma with its hopeless prognosis there is a purely localized form amenable to surgical treatment.

Localized Inflammation of Cecum and Its Treatment—Pich reports four cases of localized inflammatory process of the cecal wall in its early stages. The preoperative diagnosis in all was acute appendicitis. In three of these the appendix was entirely normal. The history of one suggested that the condition was chronic and that the operation was undertaken

during an acute flare up. The author states that, while acute appendicitis has entirely replaced the older concept of perityphlitis as an independent entity, the contributions of the last decade demonstrate beyond any doubt that the latter, though rare, does exist as such. The inflammatory process involves most frequently the cecum and the adjacent portion of the ileum. Besides the specific causes, such as syphilis and tuberculosis, the etiologic factors considered are constipation and alterations in the physical and chemical character of the gastro-intestinal juices. The resulting lesions of the intestinal mucosa become the weak spot and favor localization of pathogenic microorganisms. Chronic inflammatory tumor of the large intestine requires extirpation. With regard to the acute inflammatory processes of the intestine will there exist no sharply defined indications for the operative treatment. Extensive inflammatory involvement of the cecal wall displays a striking capacity for spontaneous healing. The author therefore considers ileocecal resection a too formidable and hardly justified procedure for such cases. In three of the author's cases a complete recovery followed conservative treatment. In the fourth a part of the cecal wall had to be resected.

Insulin-Dextrose-Water Tolerance as Liver Function Test in Rectal Carcinoma—According to Irsigler, the liver function most important from the standpoint of the surgeon is that of glycogen storage and of the carbohydrate metabolism in general. A reliable liver function test would be helpful in cases of rectal carcinoma as an indicator of patients' resistance to the infection and to cancer toxemia as well as of the existence of liver metastases. The author states that Rehn and Littel have demonstrated the existence of a lowered sugar tolerance in cancer patients. The author administered levulose to eleven patients but was forced to give it up because of the occurrence of diarrheas and of contradictory results in a large proportion of the cases. Because sugar tolerance tests are in a sense tests of the insular function of the pancreas, he adopted the insulin dextrose-water test. The technique followed was that of Morawitz and Mancke who used it in internal medicine for the diagnosis of liver cirrhosis. A sample of blood was obtained on a fasting stomach at 6:30 a. m. Ten minutes later 20 units of insulin was administered. At 7 a. m., 50 Gm. of dextrose in 500 cc of tea was given by mouth. This was followed by 1000 cc of tea or water. Samples of blood were taken at 7:30, 8:30, 9 and 10 a. m. Sugar determinations were made after the method of Hagedorn-Jensen. In normal persons the administration of dextrose is followed by a rapid rise in the blood sugar, reaching 140 mg per hundred cubic centimeters after half an hour. This is followed by a fall, which reaches its lowest point of about 80 mg per hundred cubic centimeters at the end of three hours. In normal persons the difference between the fasting blood sugar and the lowest level after the administration of dextrose oscillates between 20 and 30. In diseases of the liver the blood sugar falls to about 40 mg per hundred cubic centimeters and the difference between the fasting blood sugar and the lowest point of the alimentary glycemia was from 50 to 70. The author applied the test in eighteen cases of rectal carcinoma. In some of the cases the test had to be interrupted because of hypoglycemic manifestations caused by insulin. These manifestations in themselves as well as the marked sinking of the glycemic curve serve as an indicator of glycogen insufficiency and therefore of liver insufficiency. He likewise noted a rise of temperature during the rise of the glycemic curve and a corresponding lowering with the fall in the curve. In his opinion this hypothermia is due either to deprivation of carbohydrate reserve of the tissues or to insulin effect on the heat center

The tendency to hypoglycemic manifestations was greater in patients having liver metastases than in those without. The author feels that the test, while not free from errors, is useful in rectal surgery for the diagnosis of metastases as well as for planning two stage or multiple stage operative interventions.

Vocation and Trauma in Dupuytren's Contraction.—Schroder states that Dupuytren's contraction always develops on the basis of a congenital dysplasia of the palmar aponeurosis inadequate to sustain the demands made on it. He was able to demonstrate the hereditary nature of this condition in about 40 per cent of the carefully investigated cases. Certain irregularities noted in the hereditary transmission point to the influence of exogenous factors. The author examined 2198 persons whose occupation entails a varying degree of considerable trauma to the hands with the object of ascertaining the influence of trauma on predisposition. The incidence of contracture was many times greater in persons whose hands were exposed to severe traumatization when compared with those whose hands were exposed to little or no trauma. Thus he regards Dupuytren's contracture as a result of two factors: the congenital predisposition and the external factor of repeated traumatization of the palm of the hand. With pronounced hereditary predisposition the contracture may develop in the presence of insignificant exogenous influences. In such cases heredity is relatively frequently demonstrable. A mild hereditary taint can result in a contracture only under the influence of severe traumatization. Dupuytren's contracture resulting from a single trauma, is seen only exceptionally.

Experience with Appendicitis.—Seifert reports a statistical study of 2763 cases of acute appendicitis in which operation was performed between 1911 and 1931 at the university clinic of Würzburg. Comparison of the two decades shows an increase in the incidence of the disorder in recent years. The age incidence, however remained unchanged. The incidence of complications rises steadily within the first five days when surgical intervention is not instituted. Spreading peritonitis and abscess formation make up more than nine tenths of these complications. Pulmonary infections, venous thrombosis and embolism were responsible for only 1.5 per cent of the total mortality. On the basis of results the author feels justified in adhering to the formerly established operative indication, namely to operate as soon as the diagnosis of acute appendicitis is confirmed. The twenty-four or forty-eight hour limitation is not acceptable as an operative indication. The total mortality of the decade from 1911 to 1920 was 68 per cent. This figure was lowered to 35 per cent during the next decade from 1922 to 1931. An improvement was likewise observed in the mortality due to spreading peritonitis without tendency to localization. This mortality amounted to 69 per cent during the first decade and to 41 per cent during the second. These results have become worse in the last few years in the author's opinion principally because of the treatment of the walled-off abscess. The attitude of the Würzburg clinic regarding that complication is to wait if the fever is moderate, the pain not severe and the intestinal function satisfactory. Conservative treatment is particularly indicated in the older patients when, under the influence of rest in bed and warm applications, the temperature continues to fall and the tumor to shrink in size. When on the other hand, fever and pain persist in the course of two or three days of conservative treatment, operation should no longer be delayed. The author believes that mortality from operations performed on abscesses is due to improper protection of the general peritoneal cavity. In twenty-five fatal cases of operation for a walled off abscess, it was found that in twelve the process was one of a beginning diffuse peritonitis. In five cases of well walled-off abscess death, in the author's opinion was the result of the removal of the appendix. He shares Rehn's opinion that the treatment of the walled off abscess should be limited to evacuation of pus, with no attempt at removing the appendix. He regards the operation for walled-off abscess as one requiring much surgical experience and believes that better results will be obtained when the operation is performed by experienced surgeons rather than by young clinical assistants.

Hyperchromic Anemias in Experimentally Produced Spruelike Disturbances.—In their studies on alimentary anemia Rominger and Bomskov were able to produce two types, a chlorotic type that developed in growing white rats after feeding with cow's milk, and one that resembled pernicious anemia and developed after feeding with goat's milk. It was found also that the cow's milk anemia is due to lack of iron and copper, for the administration of these two metals cured or prevented it. The goat's milk anemia reacted just like pernicious anemia to liver and liver extracts. The main symptoms of the disorder that developed in the growing rats following feeding with goat's milk were fatty stools, pernicious anemia, lipemia and nervous disturbances that is the symptoms of sprue. It was found that the disorder can be prevented and cured by the administration of the vitamin B-complex, of liver and of liver extracts. The authors discuss the development of the spruelike disorder and of the anemia on the basis of the various theories that have been advanced. Their own studies convinced them that, although the lack of a specific food factor in the sense of Castle's principle is a contributing factor in the development of spruelike disturbances, it is not the only factor and that the gastro-intestinal disturbances, which prevent the resorption of this factor likewise play a part. They think that this opinion can be reconciled with some of the contradicting theories of the etiology, pathogenesis and treatment of the spruelike diseases and that it explains the therapeutic action of liver preparations in sprue. At any rate, the unsolved questions should be investigated further on the basis of the described experimental methods in animals with goat's milk anemia.

Specific and Nonspecific Reactions in Typhus, Cancer and Tuberculosis.—Hirsfeld and his associates summarize their observations as follows: 1. Typhus, cancer and tuberculosis serums react in a certain percentage of cases with organic lipoids, with cholesterol and with cancer extracts. If the percentage of the positive reactions of tuberculosis and cancer serums are compared with tuberculosis and cancer antigens, a greater reaction capacity with the homologous antigen becomes evident, a fact which although it does not definitely demonstrate a specific affinity, makes it nevertheless probable. 2. The different lability reactions occur in various percentages, but certain elective affinities seem to exist, for instance, the tuberculosis serums react more frequently with lecithin, the cancer serums with cholesterol. It is of practical significance that all reactions with lipoids occur less often than the lability reactions according to Daranyi. The nonspecific Daranyi reaction provides a better basis for the exclusion of tuberculous infection or of cancer than does the reaction with specific antigens. 3. The various reactions do not have strong correlations. However, there exists a certain correlation in tuberculosis between the tuberculosis reaction of Witebsky and the lecithin reaction of Sachs, as well as between Hirsfeld's cancer reaction and the complement fixation with stabilized cholesterol. 4. The Wassermann reaction may become positive in the course of cancer, when a syphilitic infection is absent. This could be considered indirect proof of the auto-antibody theory of the Wassermann reaction. 5. The Wassermann reaction in typhus differs to a certain extent from the Wassermann reaction in syphilis since it is positive only with some antigens and under the influence of heat and since the flocculation reactions develop not at all or only rarely.

Decrease of Complement Content of Blood in Allergic Diseases—According to Paul and Pely, the immunobiologic processes are dependent on the presence of the complement. On the basis of recent investigations, the complement is considered no longer as a definite substance but rather as the expression of a colloidal condition. Thus complement signifies a physicochemical state of the blood by virtue of which it has complemental capacities. The authors show that in case of a parenchymal lesion of the liver the complemental capacity of the blood decreases, and, since parenchymal impurities of the liver always exist in allergic diseases, it was logical to assume that the complement content of the blood is reduced in allergic diseases. They made this problem the subject of their investigations. They give a tabular report of the complement content of the blood detected in various allergic disorders. They consider 0.04 cc as the normal average that is this quantity of blood serum is required to effect hemolysis of 0.5 cc of a 5 per cent suspension of sheep corpuscles in the presence of 0.5 cc of a titrated hemolysin. The table shows that in allergic disorders the quantity of blood required for this purpose is much larger. The authors conclude from this that the physicochemical structure of the blood undergoes changes in allergic diseases and that these changes result in a decrease of the complemental capacity of the blood. They attempt an explanation of the decrease in the complement in allergic diseases.

Method of Animal Experimentation for Demonstration of Castle's Principle of Gastric Juice and Its Clinical Significance K. Singer — p. 200

*Therapy of Lamblasis G. E. Sincke — p. 204

Porphyrin Elimination During Normal and Pathologic Pregnancy—In studying the relationship of porphyrins to the blood pigment metabolism during pregnancy, Carrié and Herold employed the spectrophotometric determination of the urine. They found that porphyrin elimination is reduced during normal pregnancy. They think that this is due to the fact that a large portion of the maternal porphyrin is utilized in the formation of the fetal blood pigment, for during the puerperium they noted a renewed increase in the porphyrin elimination. In patients with hyperemesis of pregnancy they observed an increase in the porphyrin elimination and on the basis of parallel tests on the function of the liver they conclude that this increased elimination is the result of a functional impairment of the liver. They think that by the detection of a greater elimination of porphyrin by means of their spectrophotometric method, in patients with hyperemesis or with eclampsia, they have demonstrated a disturbance in the hepatic function and thereby have provided a new possibility for the recognition of an insufficiency of the liver.

Therapy of Lamblasis—Sincke observed that intravenous neoarsphenamine injections as well as most of the other remedies that have been recommended for the treatment of lamblasis do not produce permanent cures. Consequently he decided to resort to Lauda's method (THE JOURNAL, Dec 1 1934, p. 1743), which likewise employs neoarsphenamine but administers it not by intravenous injection but by the duodenal tube (0.3 Gm of neoarsphenamine in 200 cc. of water). He was able to produce permanent results with this procedure and recommends Lauda's intraduodenal administration of neoarsphenamine for the treatment of lamblasis.

*Problem of Lactation During Mastitis of Mother M. Schlegel — p. 191

Intraperitoneal Infusion of Native Carlsbad Mineral Water for Beginning Treatment of Toxicosis in Nurslings R. Ungar — p. 194

Exophthalmic Goiter in Children—Wallis stresses the rarity of exophthalmic goiter in children in the region of Vienna. He points out that this contradicts the American reports, according to which hyperthyroidism occurs rather fre-

quently in children. He thinks that this might be explained by local differences, pointing out that in regions in which goiter is endemic hyperthyroidism is rarer and more benign. On the other hand, he thinks that the term hyperthyroidism might be used by American authors in a more inclusive sense than it is in Vienna.

Lactation During Mastitis of Mother—Schlegel points out that the majority of pediatricians are of the opinion that the nursing should continue to nurse at the breast in the course of a maternal mastitis, because the physiologic emptying of the breast has a favorable effect on the process of inflammation and a deleterious influence on the child does not have to be feared, since an enteral infection of the nursing, as the result of the intake of staphylococci with the breast milk, is not likely. However, the author observed a number of cases which prove that the enteral infection is not the only determining factor, for in the contact between mother and nursing other ways of infection are possible. He gives the histories of three cases in which the nurslings developed suppurating infections. One of the nurslings died. It cannot be doubted that the nurslings were infected during nursing, for the foci of suppuration appeared first on the face and the oral mucous membrane and the same pathogenic agents were found in mother and child. Since every suppurating infection threatens the life of a nursing, the author advises caution particularly in the cases in which the breast of the mother has a tendency to abscess formation. He thinks that contact between mother and child should be avoided in these cases and that the child should be fed with the milk that has been drawn from the breast.

Arthritis Deformans of Costovertebral Joints P. Barcelo — p. 139

*Therapy of Anemia and Problems of Anemia A. Hittmair — p. 140

Sepsis Following Tonsillitis—Waldapfel differentiates two types of tonsillogenic sepsis. In the first type dissemination takes place directly by way of the blood stream from small thrombosed tonsillar veins and advances in the direction of the jugular vein. In the second type dissemination takes place by way of the lymph channels and along the neck and from there by way of a periphlebitis usually originating in a lymph node, with subsequent invasion of the blood stream and with secondary thrombosis of the jugular vein. Another important factor is that the port of entry is not always identical with the septic focus. The infection may originate in the tonsil, but the septic focus is frequently in the loose tissue of the parapharyngeal space. The therapy should take account of these pathologic anatomic conditions. The author has made it a rule to open and drain the parapharyngeal space from the outside and to examine the jugular vein whenever there is the slightest suspicion of infection. If the local changes in the tonsil indicate that the septic focus is within the tonsil it is removed. By this method the author has succeeded in reducing the mortality rate greatly. The clinical symptoms that indicate the infection of the parapharyngeal space are infiltration of the neck, sensitivity to pressure in the region of the jugular vein, attacks of chills and symptoms of general sepsis. If these symptoms are apparent the diagnosis and the decision to resort to an operation ought to present no difficulties. On the other hand when the local changes seem insignificant it may be difficult to diagnose the condition. The author calls attention to the jugular glands as septic foci and stresses that they ought to be removed even if there is only an inflammatory swelling.

Therapy and Problems of Anemia—Hittmair points out that the mechanism by which stomach and liver influence the blood formation is at present the most burning question in the problem of anemia. That even in so-called primary anemia the blood changes are only a symptom and not the disease itself is proved by the fact that although the modern treatment of anemia produces excellent symptomatic results it does not effect complete cure. The author mentions a number of symptoms that occur in all "primary" anemias but limits his discussion

to pernicious anemia. He calls attention to the fact that the liver and stomach therapy of pernicious anemia proved that it was an error to consider this anemia a hemolytic one. Secretory factors play a much greater part than does the hemolysis. It is known that the products of the adrenals and of the thyroid increase the action of the liver and that in some cases of hypothyroidism thyroid extract has to be administered before the liver therapy can become effective. Moreover, atrophy of the thyroid occasionally accompanies pernicious anemia, and strumectomy for the treatment of exophthalmic goiter has been known to be followed by pernicious anemia. On the other hand chlorosis and achylic anemia frequently occur with hyperthyroidism. In achylic anemia this is surprising since hypochlorhydria is usually accompanied by a hypofunction of the thyroid. The efficacy of iron likewise can be increased by a combination with secretory preparations yet it cannot be said that either reduced iron or liver or stomach extracts exert their influence by way of the hormone system. The author thinks that the spinal symptoms and the glossitis indicate that a toxin plays a part in pernicious anemia. Other toxic symptoms of this disease, such as fever disturbances in the water exchange and subjective disturbances usually disappear following stomach or liver therapy. This is probably due to a detoxicating effect. The author discusses the influence of stomach and liver on the blood formation, calling especial attention to certain embryonal conditions.

Tuberculosis of Uterine Cervix I Morillo—p 166

Endocrine Syndrome During Pregnancy and After Puerperium.—Kehrer shows that during pregnancy there usually develops a more or less pronounced hypertrophy and hyperplasia of most of the endocrine glands. This is pronounced in the hypophysis in which the characteristic pregnancy cells appear. The signs of incompletely developed acromegaly observed in some pregnant women are probably not the result of the pregnancy cell but rather caused by the simultaneous hypertrophy of the eosinophile cells. The excessive increase in the size of the hypophysis may result in mechanical pressure on the neighboring portions of the brain on the diencephalon with subsequent development of diabetes insipidus (polyuria polydipsia), or on the optic chiasm with amblyopia or amaurosis. Occasionally obesity develops by way of the cerebral cortex-diencephalon-glandular hypophysis. After the puerperium there often appear the symptoms of diencephalic-hypophyseal adiposity, the so-called adiposogenital dystrophy, the symptoms of hypophyseal cachexia (Simmonds disease) and the symptoms of progressive hypodystrophy. These disorders are caused by organic changes in the diencephalon or the glandular hypophysis (severe forms), or they are of psychic origin developing by way of the cerebral cortex-diencephalon-glandular hypophysis (mild and atypical forms). Both types are accompanied by ovarian disturbances, usually amenorrhea. Later, disturbances of the thyroid may develop which become manifest as hypothyroid adiposity or as thyrosexual insufficiency. These two syndromes are generally accompanied by hypogenitalism and amenorrhea. Then again thyrotoxicoses may develop particularly in the form of exophthalmic goiter. Pancreatic diabetes in the severe as well as in the mild form develops primarily in women who have borne several children. Its first beginnings can usually be traced to a postpuerperal period. Addison's disease has likewise been known to develop following the puerperal period. In addition to the typical there occurs an atypical form, which is designated as adrenal emaciation. The so-called multiple endocrine sclerosis a severe impairment of several endocrine glands with reduction or complete abolition of their function, has been observed frequently following a

febrile puerperal process. It is always caused by fibrous atrophy of the glandular hypophysis, which is usually followed by the development of similar changes in other secretory glands: the thyroid, the ovaries and the adrenals.

Lactic Acid Content of Blood During Pregnancy and Puerperium.—Truka points out that many investigators who study the lactic acid content of the blood during pregnancy make the mistake of comparing the values with so called normal values. He maintains that there is really no normal value, because it changes with the time of the year, with the nutrition and with the physical and psychic condition of a person. Thus it is possible to determine a change in the lactic acid content of the blood only if these factors are the same. The author's tests were made with due regard to these factors. He found that during the ninth month of pregnancy the lactic acid content of the blood increases by 40 or 50 per cent. He controlled the values also on the first days of the puerperium and found that several days are required before the normal level is reached again. He concludes from this that the increase cannot be due to a greater muscular activity.

*Hypophyseal Suprarenal Insufficiency and the Schellong-Srisower Phenomenon J Ratner—p 713

Etiology of Cryptogenetic Paroxysmal Hemoglobinuria.—Schally describes a case of hemolytic anemia with paroxysmal hemoglobinuria, which he considers as an unusual manifestation of chronic sepsis. He thinks that the case belongs to the Marchiafava-Micheli type of hemolytic anemia with hemoglobinuria. The chronic sepsis becomes manifest through continuous febrile temperatures that often assume a septic character, occasional chills, and splenic tumor with leukopenia and thrombopenia. One of the first attacks is followed by septicopyemia. Each one of the numerous attacks is accompanied by the acute appearance of various infectious foci located primarily in the accessory nasal sinuses. The author assumes that the prolonged infection caused a toxic impairment of the organs of erythropoiesis. The acute outbursts of infection cause hemolysis of the erythrocytes, the resistance of which has been reduced. He suggests that other obscure cases of paroxysmal hemoglobinuria may perhaps be explained in the same manner.

Hypophyseal-Adrenal Insufficiency and the Schellong-Srisower Phenomenon.—Observations on the paradoxical reduction of the systolic pressure during the transition from the horizontal to the erect posture in asthenic persons and reports by Schellong and Srisower induced Ratner to investigate the problem of the extracardiac disturbance of the circulatory regulation. Schellong traced this disturbance of the circulatory regulation to an insufficiency of the anterior lobe of the hypophysis. Srisower, who observed the disturbance in *tabes dorsalis*, ascribed the insufficient blood pressure regulation to a disturbance in the nervous conduction and rejected an endocrine cause. Without denying entirely the possibility of nervous involvement, Schellong remarks that Srisower's patients, who had attacks of vertigo and fainting became greatly emaciated. Ratner describes ten cases and discusses the nature of the Schellong-Srisower phenomenon in hypophyseal and interrenal insufficiency. His observations indicate that the lack of the interrenotropic hormone of the hypophysis is the most important factor in this regulatory disturbance. However he stresses at the same time the part played by the sympathetic centers. He emphasizes the necessity of watching for this symptom in spontaneous hypoglycemia. In describing a case of hypophyseal insufficiency with disturbances in the pigmentation he calls attention to suggestions Morawitz made in regard to pigment vitamins and to the fact that tetany cataract frequently concurs with disturbances in pigmentation.

Giant Infants in Maternal Diabetes—Fischer demonstrates with reports in the world literature that the infants of diabetic mothers frequently are of excessive weight. On the basis of a general analysis of the carbohydrate metabolism and of the changed metabolic conditions during pregnancy, the relations between mother and fetus, as regards the carbohydrate metabolism are discussed. It is assumed that the increased maternal blood sugar content causes an oversupply of dextrose in the fetal circulation. The placenta supposedly plays no active part in this process. Since the fetus has an adequately functioning pancreatic island apparatus relatively early during its existence, it is capable of storing the oversupply of sugar in the form of glycogen. Moreover the fetus develops beyond its normal size. The aid given to the maternal organism by the presence of a functioning fetal pancreas cannot be explained by a passage of insulin from the fetus to the mother but is rather the result of the continuous drawing off of considerable amounts of blood sugar.

Congenital Diaphragmatic Hernias in the New-Born—Lissowetzky maintains that roentgen diagnosis and systematic necropsies on the cadavers of the new born indicate that congenital diaphragmatic hernias are not as rare as is generally assumed. In the course of 220 necropsies on infants three cases of congenital diaphragmatic hernias were found, and the developmental anomaly had been the cause of death in all three cases. The author studied the developmental anomaly in a number of cases. He adheres to the newer theory that considers the diaphragmatic defect not the result of an inhibition in the development during the embryonal period but rather the result of a dissociation of the embryonal aggregations of cells that later form the diaphragm. This dissociation may be caused by a shifting of the abdominal organs or by an overfilling of the abdominal cavity by the intestine, as the result of which the organs are forced from the abdominal to the thoracic cavity. The change in the position of the organs may result from exogenic factors, such as constriction of the maternal abdomen or a push or thrust against it, or from endogenic disturbances in the embryonal conditions. The newer idea of the development of the diaphragmatic defect is of practical significance, for the opinion that the defect is not due to the absence of a portion of the diaphragm but to rending of the embryonic traces of the diaphragm makes the development of an incarceration appear likely, and it also suggests the possibility of surgical repair. In postmortem studies the author observed that after the displaced organs had been brought from the thoracic into the abdominal cavity the edges of the defect came closer together so that practically only a slit remained. He believes that early diagnosis and resorting to the proper measures will make it possible to save the life of infants with congenital diaphragmatic hernia in the majority of cases.

Diagnosis of Fetal Deformities Before Delivery—Koerner points out that most obstetricians are of the opinion that pregnancy should not be carried to term when examination during the last months of pregnancy reveals a deformity that makes it impossible for the child to live. He admits that the use of roentgenoscopy makes it much easier to recognize such deformities but he stresses that this advancement in the technique should not be a temptation to make a grave decision without careful deliberation. He describes a case in which roentgenoscopy disclosed an abnormal position, an unusually large head and a double rectangular bending of the vertebral column. The possibility of a deformity of the fetus was considered but it was nevertheless decided to terminate the delivery by a cesarean operation. The child was normal roentgenoscopy of its verte-

bral columns revealed no abnormalities, and the further development was normal. It is interesting to note that the brother of the mother is a contortionist.

Atrophy of Liver—Geil and Jørgensen discuss the clinical and anatomopathologic picture of acute subacute and chronic liver atrophy, illustrating this with ten cases. Acute parenchymatous degeneration of the liver may cause death in the acute stage, heal completely or take a protracted or recurrent course. The degenerative processes go hand in hand with regeneration and proliferation of the connective tissue and in atrophy of the liver may be transformed in different ways. Because of the varying clinical picture considerable difficulties in differential diagnosis may arise. In protracted cases, ascites and disturbance in the portal circulation may develop, causing the clinical picture to resemble that of liver cirrhoses. The intermittent course in protracted cases not infrequently results in intermittent jaundice and severe colic-like pains in the hepatic region, so that confusion with cholelithiasis may occur. A third clinical form of liver atrophy appears in certain subacute and chronic cases in the guise of a progressive cachexia, simulating cancer in the liver or bile ducts. This condition is due to deficient liver function with autointoxication. The galactose test sometimes fails in the acute forms of liver atrophy, in the more protracted cases the outcome is usually negative probably because the pseudotubuli formed in the regenerative phases can assimilate the galactose. Although the prognosis in liver atrophy must as a rule be considered grave at the start, the possibility is not excluded that energetic medical treatment with sugar and insulin may in some cases delay the development of the process and possibly even check it. As operative intervention, even exploratory laparotomy, is not well borne by patients with liver atrophy, the attempt should be made by means of other tests of the function of the liver or biliary tract to reach a more certain diagnosis. While the causes of the development of liver atrophy are uncertain, the authors are inclined to think that it may be due to a number of highly different intoxications and infections.

Chaulmoogra Oil Treatment of Mycosis Fungoides—Lomholt asserts that, in the stage of mycosis fungoides in which the infiltrating erythema is about to be followed by tumor formation, chaulmoogra oil exerts a remarkable influence. In the four cases reported the treatment has, at least temporarily, led to complete or almost complete freedom from the symptoms. In addition to its action on mycosis fungoides, chaulmoogra oil seems to affect other forms of granulation tissue in the skin, such as certain forms of tuberculosis, Boeck's sarcoid and granuloma annulare.

Unspecific Chronic Epididymitis—Bræstrup says that in the majority of cases this disturbance is due to transplantation by the canalicular route of an inflammation from the urethra. The symptoms in chronic and subacute epididymitis resemble those of tuberculous epididymitis and clinical distinction may be impossible. Treatment consists of rest in bed and elevation of the scrotum for from eight to ten days. In the mild cases, in which the symptoms tend to recede rapidly, conservative treatment is continued. In the other cases, resection of the epididymis with the vas deferens is then done. Urethritis was confirmed in six of the eighteen cases reported and in three there was pyuria. Five had a history of trauma. Fourteen were treated surgically. Hemicastration was necessary in only one. The diagnosis was verified microscopically.

BILATERAL URINARY CALCULI

WITH SPECIAL REFERENCE TO THERAPEUTIC
PROBLEMS

ALEXANDER R. STEVENS, M.D.
NEW YORK

The therapeutic problems peculiar to bilateral urinary calculi are not solved by the application of stated formulas. A few of these, such as operate first (a) on the side of the better kidney, or indeed (b) in certain groups of cases on the worse side, or (c) on the side of recent pain, have become popular and are frequently repeated. My feeling is that these so-called rules do not deal with primary factors but are expressions of frequent secondary effects of these factors and at times may be quite misleading. My purpose in this paper is to point out what I believe to be the more fundamental principles involved, a study of which in a given case should govern therapeutic decisions.

The presence of calculi simultaneously in the two upper urinary tracts is not uncommon. In published series of cases of urinary lithiasis the percentage of bilateral calculi diagnosed clinically has varied between 8 and 20. Joly¹ recently stated that autopsy records show nearly 50 per cent. Hence this subject is one demanding frequent discussion.

In clinical work one must secure data as complete as possible concerning the patient in general and his urinary tract in particular. The symptoms are sometimes valuable but are not infallible guides in therapy. The size and location of all calculi should be known, whether or not they obstruct, as well as the total renal function, the relative function of the two kidneys, and the presence or absence and degree of infection of both kidneys. Knowledge of all these factors is most important before judgment is rendered of whether to take any action and what.

There is no dependable method of dissolving calculi, but stones may pass spontaneously through the urinary channels or be removed by operation. If the latter procedure is contemplated, one must be sure that the probable benefit justifies the risk. Accordingly there is general agreement that operation is not advisable on calculi in some locations and under certain conditions. Moreover, one must be clear in one's mind on this subject, remembering that considerations applicable to unilateral cases will usually apply equally well to each side in bilateral ones, although the latter may need closer observation.

Large, noninfected, nonobstructing, symptomless stag-horn calculi are usually left alone. Also, there is questionable advantage in trying to remove a large mass of nonobstructing, symptomless small stones occupying an entire kidney; it is nearly impossible to find them all, even with roentgen control at the operation table, and the kidney is badly mutilated in the attempt. There is no hurry in operating for small, symptomless stones in a kidney even in the presence of a low grade infection (they are located with difficulty at operation, and, moreover, there is strong probability of spontaneous passage), whereas one does not dare wait long for the spontaneous passage of ureteral calculi associated with urinary infection. Stones of moderate size that are trapped in a calyx need not be disturbed unless there is also persistent infection or symptoms.

In such cases therapy may include little more than occasional observation, including roentgen examination during a period of patient waiting. I seek to avoid infection in noninfected cases by general care, by avoidance of constipation and by the clearance of any foci of infection found in the body. When inflammation is present one should, in addition to the foregoing, try to improve the infection by cystoscopic methods and the use of antiseptics by mouth, although entire relief is not often obtained without the removal of associated calculi.

What are the reasons for operating in urinary lithiasis? Objectively, (a) calculi of the upper urinary tract are a most serious menace when they obstruct the urinary flow, (b) they are potent in prolonging infection, and (c) they may cause pressure atrophy of the parenchyma by growth of the stone. The first two factors are the important ones and the ones that most frequently demand intervention. Obstruction, particularly when complete, causes dilatation above with gradual destruction of kidney substance, encourages the advent or rapid spreading of infection, and may urgently demand relief. Nonobstructing stones, even when associated with chronic infection permit more procrastination, while the fear of renal atrophy by growth of calculi, in the absence of infection, rarely calls for operation. One or more of these factors are usually noted when symptoms are present, yet cases do occur in which pain or hemorrhage alone is the chief indication for treatment.

On the other hand, the risks of the proposed therapy must be considered fairly. Relief of obstruction by a ureteral catheter, if possible, is usually a relatively harmless procedure, it may give temporary relief from symptoms and danger, may be followed by spontaneous passage of a calculus and will at least improve the patient's condition for subsequent operation, should that be needed. Ureterotomy is one of the least danger-

923-936 (May) 1933.

ous major operations. Pyelotomy entails an added risk, and nephrotomy, particularly if extensive, is decidedly more dangerous. Sometimes, to reduce the danger, drainage alone with perhaps removal of the most obstructing stone, if easily obtained, is all that is advisable. I am convinced from a study of postoperative figures for nonprotein nitrogen that as a rule ureterotomy and pyelotomy cause no immediate or remote decline of renal function, whereas in some cases nephrotomy has been followed by a decided, though perhaps transient, retention of nonprotein nitrogen in the blood (once to 100 mg.) within a week or ten days. Large and multiple incisions in the kidney cortex requiring deep sutures will also probably destroy permanently a part of the cortex. Moreover, secondary hemorrhages and acute kidney infections, when they do occur after operation, are usually encountered after nephrotomy incisions and not after pyelotomy. I feel that fewer untoward results will follow multiple small nephrotomy incisions than one large one and that better results are obtained if no suture of these small wounds is made except to control hemorrhage. Moreover sutures should preferably be confined to the kidney capsule, should be underpinned with fat or muscle,² and as few deep ones should be used as possible.

With these pros and cons in mind each case of bilateral calculi is reviewed as an individual problem. How can the maximum benefit be offered to the patient with the minimum risk? The answer to this question determines the type of therapy, whether operation (if needed) is done primarily on both sides or only on one if the latter, which side should be attacked first. The side to be operated on first may or may not be the one giving better renal function tests at the moment. Even if one could determine which kidney has the greater potential function (which cannot be done), that would not always be the side to be operated on first. As stated before, in occasional instances one will not offer initial relief to the side with recent pain, contrary to oft expressed advice. I do not decry the helpful value of symptoms and of the determined relative kidney functions when wisely interpreted but urge particularly that one seek more fundamental reasons for one's decisions rather than follow the time honored formulas.

The knowledge possessed of the probable improvement of renal function or infection as a sequel of operation will also influence the urologist. The more nearly complete urinary obstruction is, the more rapidly will kidney injury occur. The greater this injury, the less the return of function to be anticipated following operation. Unfortunately, one's ability to judge of a kidney's potential possibilities is far from perfect, and I was sorely disappointed in one case because no augmented function could be demonstrated after ureterotomy with removal of a stone, although the primary purpose was a gain of renal function. In instances of bilateral obstructing calculi, in which bilateral operation seems inadvisable, one may theoretically argue in favor of operating first on the side with symptoms of longer duration and usually temporarily lower function, to allow the corresponding kidney a better chance to approach normal, realizing that primary relief of the other side will make that side assume even more of

the function of its mate and retain it permanently. (This principle has been repeatedly demonstrated experimentally by Hinman and has been referred to in many papers.) But in such cases one is often dealing with a sick patient and must relieve first the side more recently obstructed, thereby risking a partial functional loss of the other side, as a live patient is preferable to a theoretically well conceived plan of operation.

If nephrectomy will obviously be required on one side, this may well be the primary operation in a septic patient, but usually it is wiser to relieve the other kidney of calculi first and permit its full restoration before doing the nephrectomy.

And so one might run on with special problems requiring individual judgment. Thus it is that in the literature numerous groupings of various combinations, according to the ideas of the author, are offered with the appropriate management. The advice offered is usually sound but the multiplicity of possible combinations is confusing. Hence I urge that less attention be paid to groupings and to rules and formulas, but that treatment be based on a knowledge (a) of the principles involved (b) of facts determined by history and examination with more emphasis laid on the location and size of calculi, the total renal function and the presence of infection than on tests of relative renal function, (c) of the immediate and remote needs of the patient and (d) of the probable risks of various lines of treatment. The immediate needs may overshadow the ultimate good, but always the general aim should be to render the greatest service with the least risk.

This communication is offered after a study of the literature³ and a careful review and tabulation of thirty-five cases (all but three of which are from the urologic service of Bellevue Hospital) of simultaneous bilateral calculi of the upper urinary tract, which came to operation at my hands. Excepting two earlier records, all cases were seen between 1921 and 1934. I do not include those patients who did not receive surgical treatment, some refused treatment or even examination, treatment was not advised in others because of a concurrent serious medical ailment. One man, deemed beyond surgical aid, was uremic, with very high nonprotein constituents of the blood, ribbons of pus oozing from both ureteral orifices, and a stag-horn calculus on one side and recurrent multiple stones

in the other kidney which had been operated on else where two years earlier. There was one patient who passed spontaneously bilateral ureteral calculi following cystoscopic manipulations. Three of the excluded group were operated on by us on one kidney only, after nephrectomy elsewhere for calcareous pyonephrosis.

Fig 1—Simple roentgenogram of a woman aged 40, much pain in the left flank for the past two weeks, similar attacks for four years. There was no urinary disturbance. Marked tenderness of the left kidney with fair function and some infection. The right ureteral orifice was not found; no indigocarmine was seen in twenty minutes; an intravenous urogram showed good output from the left kidney and none from the right. Large calculi in the lower right ureter and stag horn calculus in the left kidney. Pain and tenderness in the left kidney became less in the hospital. Right ureterotomy was done with removal of two calculi. Intravenous urograms two weeks after operation showed slight excretion from the right kidney. The operation was done on the side showing poorer function and not on the painful side. The object was improvement of total renal function by ureterolithotomy, an operation of little risk. Later operation was advised on the left kidney.

In only three instances were simultaneous bilateral operations performed, all the patients survived. This bilateral procedure is preferable in young and robust patients who are good operative risks, and with rapid operations not requiring extensive nephrotomy. Hrytschak⁴ has reported seven one-stage operations in fifteen bilateral cases. The advantages of one over two operations are evident: shorter stay in the hospital, briefer convalescence, less expense, and the like. However, most of our patients apply for treatment late and are in poor condition.

There were five deaths after the first operation performed on the other thirty-two, four among the first twenty-one and one among the eleven seen during the past five years. These will be reported critically but briefly, particularly to discuss the treatment in certain cases.

CASE 1—A man, aged 54, who was very ill with stones in both kidneys, died three days after simple incision of a perinephric abscess. No attempt was made to do anything to either kidney. His nonprotein nitrogen was over 200 on the day of operation.

⁴ Hrytschak, T. Operations in One Sitting for Bilateral Calculi. *Deutsche Ztschr. f. Chir.* 225: 229-241, 1930. *Operative Treatment of Bilateral Nephrolithiasis.* *Surg. Gynec. & Obst.* 58: 103-112 (Jan.) 1934.

CASE 2—A man, aged 43, died from shock following a difficult intracapsular nephrectomy through the scar of a former kidney operation. There was a long history of frequent colic on both sides, a litholapaxy and the renal lithotomy already noted. He had had recent severe pain on the operated side which showed infection and reduced function without any evidence of ureteral obstruction. The better kidney contained a large stag horn calculus. We believed the painful kidney to be of little real value and operated to relieve symptoms. The error was in surgical judgment, the operation was prolonged to the large vascular pedicle because of the optimistic report on the general condition (not justified) given by the anesthetist.

CASE 3—A man, aged 34, died on the fifth day following removal of the very adherent right pus kidney, as the result apparently of extreme abdominal distention. The patient had a large dendritic calculus in the right kidney which gave thick pus, no urea and no dye; there was a large rounded calculus in the left kidney, the excretion from which contained no pus and yielded a good urea percentage and phenolsulphonphthalein in seven minutes. We elected to remove the worthless kidney which was causing pain. I believe it would have been wiser simply to drain this kidney by nephrostomy to relieve infection and pain and then remove the calculus by pyelotomy from the left kidney before attempting right nephrectomy.

CASE 4—The fourth death occurred three days after pyelotomy with removal of a stone. A man aged 53, was admitted in 1923 with anuria of twenty hours duration following a drunken debauch. Indwelling ureteral catheters brought urine from both kidneys and were left in situ for three days, at which time the patient insisted on going home. Normal urination continued for four days only and was followed by three days of anuria. The patient returned to the hospital and bilateral catheters were again introduced. The next day the nonprotein nitrogen was 84 mg per hundred cubic centimeters of blood and creatinine was 4.5. Five days later (the catheters having been withdrawn) the nonprotein nitrogen was 230 and catheters were

Fig 2—Intravenous pyelogram before operation (same case as in figure 1).

reintroduced. Several phenolsulphonphthalein tests done at various times gave zero output in two hours. Roentgenograms showed small shadows at the ureteropelvic junctions on both sides. Several times the catheters were withdrawn, anuria ensued, and the catheters were reinserted. But the cystoscopic treatment could not be continued indefinitely. On the twenty-fifth day in the hospital the nonprotein nitrogen was 56 and

creatinine 32, the best report on the record. The situation was desperate, but some type of drainage was urgently needed. I doubt whether any operation would have saved this man, but, theoretically, with our present views rapid bilateral nephrostomy would seem indicated and undoubtedly would have been permanent. However, we operated on one side only and performed right pyelotomy with removal of one obstructing stone, considerable perinephric edema was noted. Autopsy revealed a small right kidney with recent perinephritis and calcareous

Fig. 3—Simple roentgenogram of a man aged 31 who had no pain or urinary symptoms, the general symptoms including high blood pressure, headaches and flushing of the skin. Function tests of the right kidney were little better than the left. Total phenolsulphonphthalein output was 25 and 15 per cent for two hours; nonprotein nitrogen and creatinine of the blood were normal. Multiple calculi of both kidneys were found with large stones in both pelves. Left pyelotomy and multiple nephrotomy incisions were done; more than 200 stones were removed. Oliguria occurred, followed by death on the third day after operation.

incrustations in the thickened wall of the corresponding ureter, 2 cm below the pelvis, the left kidney was large and badly infected and there was an obstructing calcific deposit at the ureteropelvic junction.

CASE 5—The most recent death (1931) followed three days after left pyelotomy and multiple nephrotomy performed on a man, aged 31 (fig. 3). More than 200 stones were removed. Judging from the roentgenograms, the other kidney contained as many calculi. Before operation the nonprotein nitrogen was normal and the total phenolsulphonphthalein output was 20 per cent and 20 per cent for the first two hours. The kidneys were of about equal functional value. Postoperatively, in spite of the administration of much fluid, the urine output was very scanty; the nonprotein nitrogen rose steadily and the patient died on the third day.

In case 5 we were influenced by the youth of the patient, the presence of symptoms indicating renal insufficiency in spite of apparently satisfactory tests, and the dismal prospect without operation. The grave risk was appreciated, but we hoped to prolong life and make it more comfortable. It is now obvious that too much was done. We should not have undertaken more than the removal of the large pelvic stones and drainage of the kidneys at first, if indeed we should have operated at all. Although complete removal of all stones in such a kidney is well nigh impossible, we were led to attempt it by the fairly satisfactory function tests on the one hand and the desperate outlook on the other.

Only eleven of the twenty-seven patients with bilateral calculus who had survived operation on one stone-bearing kidney or ureter came to operation on the other side. It was advised in many other cases but declined by the patients because of lack of symptoms. The second operations were performed at intervals varying from seventeen days to a year after the first operations. As a rule, the procedure consisted of removal of calculi and drainage. Nephrectomy was required but once, recovery was rapid. Only nephrostomy was done on the second kidney but once, the opposite kidney had failed to resume function after ureterotomy for obstructing calculus three months earlier, and it was impossible without grave risk to remove the multiple and stag-horn calculi from the second kidney, which was tightly embedded in a mass of tough fibrous tissue. This patient is still in the hospital, walking about two months after operation, and he will be sent home wearing a nephrostomy tube.

Most of the eleven patients had an easy convalescence after operation on the second kidney. There were two deaths, however, and I would stress their parallel histories. Both patients were admitted in a precarious condition, as they had failed to return for the second operation until driven to the hospital by pain due to calculus obstruction and infection of the kidney. One died (in 1921, a year after the first operation) of renal insufficiency and infection eighteen days after removal

Fig. 4—Simple roentgenogram of a man aged 36. Many stones were passed following ureteral colic on both sides during the past year; for four months he had been in another hospital with acute multiple arthritis, septic temperature and frequent right renal colic with passage of stones very ill on admission. Thick pus from the right ureter and practically no function of the right kidney; little pus from the left kidney and fair function. Total phenolsulphonphthalein output 25 and 15 per cent. Large groups of calculi in the right kidney and many small stones in the left. Right nephrectomy was performed with prompt and marked improvement in the general condition and acute joint pains. During the next six months he passed spontaneously all but two stones from the left kidney. Total phenolsulphonphthalein output for two hours eight months after operation was 58 per cent. The purpose of the operation was relief of acute sepsis.

of a stag-horn calculus through multiple nephrotomy wounds. The other returned to the hospital three months after right ureterotomy, with fever and acute

left-sided pain. He died nine days after pyelotomy for removal of stones from the left pelvis and upper ureter drainage of a peripelvic abscess, decapsulation of the kidney and drainage of cortical abscesses. There was suspicion of pneumonia before operation but the signs were not clear and the need for relief of the kidney was urgent. Operation was done under spinal anesthesia. Pneumonia and empyema of the left side

Fig. 5—Simple roentgenogram of a man aged 44, dull pain in the right flank for the past two or three weeks with no other history of pain or of any urinary frequency. Function of two kidneys about equal slight bilateral infection. Two large calculi in calices of the right kidney with faint diffuse shadows in the lower pole, one large calculus in the lower major calyx of the left kidney with diffuse shadow in the lower pole. No stone in either renal pelvis or ureter proved by urograms. Left nephrotomy was done for stone and resection of the lower quarter of the kidney for latent tuberculosis. The patient did not return for further observation. With no stone in either ureter or kidney pelvis and with equal bilateral infection and equal function the side requiring less surgery for stone (resection was not contemplated) was attacked first.

were evident some days later. Operation, before the onset of acute symptoms set in and not required as an emergency measure, would probably have led to an easy convalescence.

As an example of successful primary nephrectomy performed to relieve sepsis—the urgent need in this case—I cite the following. A man (fig. 4), aged 32, had suffered for months with multiple acute infectious arthritis and had a high septic fever daily. He had multiple renal calculi with infection on both sides, but fewer stones, much lighter infection and better function on the left. The right kidney was removed with immediate relief of fever and the arthritis. However, there was no very large stone in the better kidney and none in the pelvis to cause obstruction, as was the case in the two patients who died following primary nephrectomy. To our amazement, most of the stones from the left kidney passed spontaneously during convalescence.

The following is of peculiar interest from the diagnostic point of view. A man, aged 32, showed by roentgenograms multiple calculi in the right kidney and one large stone apparently in the pelvis of the left kidney. Much more urine was obtained by catheter from the right ureter than from the left, and a larger

amount of phenolsulphonphthalein was recovered from the right side. However, the percentage of urea and the concentration of the dye were much better on the left side. These observations were confirmed by a second cystoscopy. The conclusion was that the left kidney was of better quality than the right but very small. At operation an infantile kidney was found on the left side and the stone removed from its pelvis. The right kidney was immediately exposed and a large group of stones removed from that side. The patient went home comfortable and apparently in good condition but returned to the hospital in about six months and died of uremia twelve days after nephrostomy was done on the right side.

We had but one instance of nephrectomy required for hemorrhage following nephrotomy for calculus. In one patient (fig. 5), we resected the lower third of a kidney because of old tuberculosis, after removing stones from the upper part of the organ.

The relative functions of the two kidneys at the time of examination have been tabulated, the side of the first operation being noted. There were twelve primary ureterotomies for stones on the side of poorer function, as indicated by the tests (we compare the urea percentage and the output of phenolsulphonphthalein or indigo-carmin as a routine), and none on a side presenting better function. Primary pyelotomy (with additional nephrotomy at times) was done six times on the poorer side, four times on the better, and six times when the two kidneys gave equal function tests before operation. Primary nephrectomy of a

Fig. 6—Bilateral calculi with double pyelograms (same case as in figure 5).

poorer kidney was done three times. This is probably not good practice when a calculus in the other kidney is so situated that it may obstruct and particularly if it is possible to remove that calculus without mutilation of the kidney substance.

When pain in either kidney region was a complaint at the time of admission to the hospital, our reasoning as outlined has led us to operate on the painful side in most cases. Yet in three patients we deliberately operated first on the nonpainful side, and in one man

SUMMARY

1 The conclusions presented here are based on a study of the literature and on a review of thirty-five cases of bilateral urinary calculi in which operation was performed

2 Full history, careful general examinations and especially painstaking and complete urologic examination are necessary

Fig 9—Simple roentgenogram of a man aged 40 entered medical wards with bronchitis has had three attacks of renal colic last one five years ago but no urinary symptoms now. Total phenolsulphonphthalein output was 10 and 10 per cent for two hours the right kidney showed slightly better function than the left. Multiple calculi in the right kidney and long one in the upper ureter single stone in the upper pole of the left kidney, and long one in the upper ureter slight infection on both sides. Left pyelotomy and one nephrotomy incision nine days later function of the left kidney was more than twice that of the right and general phenolsulphonphthalein output was 20 and 5 per cent. Seventeen days later right pyelotomy and multiple nephrotomy were done. In six months the general phenolsulphonphthalein output was 25 and 20 per cent. Operation was performed primarily for improvement of renal function and was done first on the side requiring the least damage to the parenchyma in removing calculi (and incidentally that with slightly lower tests)

3 Operation may not be advisable, or one may operate primarily on both sides or on one, depending on conditions

4 One must not be blindly guided by rules and formulas—such as, operate first on the side of the better kidney, or of the worse kidney, or of the most recent pain—but the therapy proposed must depend on a clear knowledge of the objectives sought, immediate and remote, of the means of attainment of these objects and of the risks involved. I urge careful consideration of the relative dangers of various operations in a given case

5 Data on a series of thirty-five operative cases of bilateral calculi especially illustrate the fallibility of commonly accepted rules

6 One should seek improvement of renal functions, primarily and eventually, control of infection and alleviation of symptoms. The first motive is usually outstanding, but relief of acute infection may demand initial attention, even nephrectomy

ABSTRACT OF DISCUSSION

DR JOHN S LEWIS JR Youngstown Ohio There is no rule of thumb that will serve as a guide in the management of bilateral urinary calculi. Each case is a law unto itself. Dr Stevens's keynote "Render the greatest service at the least risk" is the only guiding rule to be accepted. I would make a plea for a more general use of nephrostomy in these very sick patients. In certain cases permanent nephrostomy may be the only answer. After nephrostomy, which at first may have been considered as a permanent procedure, the benefit will be so great to the patient that further operative procedure may be considered with safety. Dr Stevens has not considered nonopaque calculi. While the general principles apply one has to exercise unusual caution as the size, location and number of stones cannot be accurately estimated. In those cases of bilateral urinary calculi which occur as the result of disturbance of the function of the parathyroid gland, the stones are small and are scattered throughout the parenchyma as well as along the excretory channels. The stones are of calcium phosphate multiple bilateral and usually small. Their arrangement is rather characteristic. These cases present the additional problem of correction of the underlying cause which is a disturbance of the function due to a tumor of one or more of the parathyroid glands. This may be accomplished by surgery, which is very difficult, or by properly given and adequate irradiation. I cannot say that I agree with Dr Chute as regards the results of irradiation in parathyroid disease. I feel that definite results are being obtained.

DR MOSSES SWICK New York Dr Stevens's presentation of this trying and often discouraging condition illustrates the serious nature of the disease. The usual life history is that marked by bilaterality, recurrence, infection and renal insufficiency. For these reasons and because of difficulties encountered in coping with this problem, every attempt at conservatism directed toward the maintenance of kidney reserve both in the

Fig 10—Simple roentgenogram of a man aged 48 with occasional hematuria for six months but no pain. The function of the kidneys was good and equal neither being infected. Medium nonobstructing stone in the right major calyx large stone in the left pelvis and major calyx. Left pyelonephrotomy was done. The patient went home and did not return for operation on other side. The first operation performed on stone most apt to cause damage by obstruction

diagnosis and in the preoperative and postoperative care, must be made. Because practically all cases of bilateral renal calculi are for the most part composed of calcium phosphate and oxalate and are therefore radiopaque retrograde pyelography not only becomes unnecessary in many of these cases but may be dangerous to an already compromised kidney reserve. Thus in cases of bilateral renal calculosis in which in many instances

the renal reserve is already compromised, retrograde pyelography may be the turning point in the death of the patient in bringing about either uremia, urosepsis or both. Since in cases of bilateral renal calculi one frequently encounters the staghorn soft and fragmented type roentgen control at the operating table as an adjuvant in the handling of such cases becomes apparent. Only by this procedure can one evaluate the end results and hope for a total removal of the calculi at the time of operation. Furthermore a clear insight into the general constitutional laboratory and clinical status of the patient is important. Determinations of water and nitrogen balance and the blood carbon dioxide chloride and calcium content should be carried out, and therapy directed along these lines. The treatment of the patient should not cease with the operation but should be followed jointly by the metabolist and urologist along lines such as: 1. Exhibition of the vitamin A diet considering the possible relationship of hyperparathyroidism to renal calculi. In this connection it might be helpful to consider also the possible relationship of phosphaturia and its causes. 2. The importance of constant forced intake of fluids. 3. The reaction of the urine and the chemical composition of the stone removed which should be determined in order to prescribe diets and medications more intelligently. 4. Finally in the presence of infection after removal of stones, use of the ketogenic diet.

PRODUCTION AND SOLUTION OF URINARY CALCULI

EXPERIMENTAL AND CLINICAL STUDIES

CHARLES C HIGGINS M.D.
CLEVELAND

Investigations dealing with the experimental production of urinary calculi have been reported in previous communications.¹ In a high proportion of albino rats maintained on a diet deficient in vitamin A, urinary calculi developed. If the deficiency in the diet was continued for a period of 250 days 85 per cent of the experimental animals exhibited vesical calculi and 42 per cent showed renal calculi. The spherical, light brown calculi varied in size from 0.5 to 8 mm in diameter. They contained calcium phosphate chiefly, with traces of carbonates and a small amount of mucoid substance. No oxalates or uric acid were detected.

METHODS OF PRODUCTION OF URINARY CALCULI

Three constant changes were observed in the experimental animals that might be associated with calculous formation. They are (1) keratinization of the epithelium of the genito-urinary tract, (2) urinary infection and (3) alkalimuria.

1. The keratinization of the epithelium is noted after the diet has been deficient in vitamin A for a period of from eight to ten weeks. This is not confined to the genito-urinary tract but involves also other mucous membranes, such as the trachea, bronchi and vagina.

This experimental study is in accord with clinical observations. Wilson and DuBois² in 1923 noted at autopsy that infants who had died from intercurrent infection associated with vitamin A deficiency demonstrated keratinization of the epithelium of the trachea, bronchi and other mucous membranes. Similar obser-

vations were reported by Mori³ and recently, in necropsies on eleven infants who had vitamin A deficiency and died from some infectious process, Blackfan and Wolbach⁴ found metaplasia or keratinization of the epithelium of the pelvis of the kidney and ureter in seven instances.

2. Urinary infection is produced in a large percentage of rats maintained on a diet deficient in vitamin A for long periods of time. Infection of the bladder occurs usually after thirty days and renal infection after from sixty to ninety days. When the experiments have progressed for from 200 to 250 days, 72 per cent of the rats have bladder infection and in 42 per cent of these there is a coexistent renal infection. The organisms isolated in dextrose brain broth were streptococci, staphylococci and mixed cultures.

Fig. 1—White rat 187 days old. A, stone in bladder and two stones in kidney after diet deficient in vitamin A. B, disappearance of renal and bladder stones after high vitamin A feeding for a period of two months.

3. Alkalimuria is a constant finding in rats maintained on a diet inadequate in vitamin A. By the addition of ammonium chloride to the diet the incidence of calculi is decreased. Likewise, by adding vitamin A to the deficient diet the urine becomes acid and calculi are not produced.

SOLUTION OF URINARY CALCULI

It was demonstrated in earlier experiments that, if vitamin A alone was restored to the diet of rats, the formation of urinary calculi could be prevented. In order to determine whether stones already formed could be dissolved by the administration of vitamin A, thirty

rats with bladder or renal calculi were studied. Except for the addition of cod liver oil, the diet remained the same as when the calculi were produced.

Twelve rats with vesical calculi had the deficient diet for from thirty to sixty days. In eleven of these the calculi had entirely disappeared roentgenographically after two drops of cod liver oil had been administered daily for a period of from fifty to sixty days. The other rat died shortly after the experiment was started. Cultures taken when the rats were killed showed no evidence of urinary infection. Sand was present in the bladders of two rats. A mild degree of keratinization of the epithelium of the genito-urinary tract was present in seven rats, in the others the epithelium appeared normal.

In a second group of eleven rats that had been on the deficient diet for from ninety-six to 130 days vesical calculi could be demonstrated roentgenographically and coexistent renal calculi were observed in two rats. After the rats had been on the high vitamin A diet for ninety days (two drops daily) roentgenograms showed no evidence of calculi in the bladders of six rats. In the other five the calculi were definitely smaller. One of the renal calculi could not be demonstrated. Cultures from the bladder were positive for mixed infection in every animal of this series, and in three animals there was infection in the kidney. There was a large abscess between the bladder and the abdominal wall in one animal but no other gross pathologic changes were noted in the genito-urinary tracts. Some degree of epithelial keratinization was present in all the rats in this series, but there was found to be evidence of repair of the stratified to normal epithelium in six rats.

The third group of twelve rats had been maintained on the deficient diet for a period of 180 days. Vesical calculi had been demonstrated in all these rats and renal calculi were present in two of them. In four animals the vesical calculi had entirely disappeared 101 days after cod liver oil (two drops daily) was added to the diet. In the remaining rats in this series the calculi were definitely smaller. In one the renal calculi also had disappeared (figs 1 and 2). The rats were killed after 107 days, and organisms were isolated from the bladder in all instances. A pure culture of staphylococcus was found in two and mixed infection in the others. In eight of the rats a coexisting renal infection was found.

Cystitis, hemorrhage under the mucosa of the bladder and renal infection were common observations in this group. Keratinization of the epithelium was present to some degree in the genito-urinary tracts of all the animals in this series. A reparative process was evident in the epithelium of the ureters, kidneys and bladder, especially when there was not a marked degree of infection. Vesicular degeneration of cells and hemocytic infiltration above the layer of undifferentiated cells, as described by Wolbach and Howe,⁵ were present in numerous instances.

These experiments show that with the addition of vitamin A to the diet there is a tendency toward restoration of the normal epithelium, along with solution of the calculi. In our first experiments at the clinic, the calculi produced in rats on a vitamin A deficient diet

were composed chiefly of calcium phosphate, so it seems logical to assume that the calculi in this series of experiments were of the same composition.

CHEMICAL FACTORS IN THE FORMATION OF CALCULI

Schade⁶ and other colloid chemists have described certain conditions necessary to the formation of calculi. These include precipitation of crystals from a supersaturated solution together with some organic colloid material, such as fibrin and mucin, which can form the nucleus of minute calculi. These, in the presence of stasis and infection, can accrete to stones of much greater proportions.

In vitamin A deficiency, then, are produced the essential conditions for calculus formation, the precipitation

Fig. 2.—White rat, aged 192 days. A, two large lamellated stones in the bladder produced on vitamin A deficient diet. B, stones entirely disappeared after high vitamin A feeding for six weeks.

of crystals from a supersaturated alkaline urine and the formation of local irritation, sometimes to the point of ulceration, consequent to keratinization and desquamation of the epithelium of the urinary tract.

Precipitation, per se, causes sediment and not stones. Neither do the desquamated epithelial cells alone act as nuclei for the formation of calculi. But the keratinization of the epithelium causes sufficient irritation and local lesions producing fibrin and mucin to form a framework for the deposition of crystalline sediment and subsequent development of stones.

These factors explain the formation of urinary calculi in experimental animals deprived of vitamin A and also in patients who have had inadequate diets. Stone areas or regions in which urinary calculi are unusually prevalent have been noted by various clinical observers.

and have usually been attributed to some rather general dietary deficiency peculiar to the region

CLINICAL OBSERVATIONS

Since these experimental investigations were undertaken, it has been the routine procedure at the Cleveland Clinic for the last two years to administer to patients who have been operated on for urinary calculi a special acid ash diet high in vitamins especially in vitamin A. Vitamin A is also added in the form of cod liver oil or halibut liver oil a teaspoonful three times a day. The various capsules containing these sources of vitamin A usually four daily also may be used. Generally this diet suffices to render the urine acid. If the urine remains alkaline, neutral or only slightly acid however acidifying agents such as ammonium chloride or sodium acid phosphate are administered. The patient is instructed to test the urine morning and night with litmus paper and on each visit to the clinic a urinalysis including the pH is made. Of course other therapeutic measures such as the eradication of renal infection or the elimination of stasis in the urinary tract have not been neglected. On this regimen no calculi have recurred but insufficient time has elapsed to warrant definite and final conclusions as to the efficacy of this prophylactic measure.

Seven patients with renal calculi, either unilateral or bilateral, who have refused operation or in whom surgical treatment was not feasible have been taking a similar diet. In each of two instances a small stone in the lower calyx of the kidney too large to pass spontaneously, has disappeared entirely within four months, according to roentgenographic examination. In two

323 small calculi were passed (fig 4). Previously this patient had never had colic nor had he passed sand or a stone in the urine. The other two patients have been on the diet for only a short time.

Several other physicians have used the acid ash diet and vitamin A in the treatment of their cases, and the collected series in which calculi have disappeared now numbers eighteen. Detailed reports of these cases will appear in a later publication.

This series is too small and insufficient time has elapsed to permit definite conclusions regarding the

FIG. 4.—A kidneys, ureters and bladder of a man aged 59 showing right renal calculus. B six months later there was a definite breaking up of the lower portion of the stone. C ten months after beginning treatment there was a marked decrease in the lower portion of the stone. The patient has passed 323 small stones.

clinical value of the method but the outlook for medical treatment at least in some cases of urinary lithiasis, seems promising.

SUMMARY

- 1 Urinary calculi develop in albino rats sustained on a diet deficient in vitamin A, and alkalimuria and keratinization of the epithelium of the urinary tract are constant observations. Infection of the urinary tract is frequent in the later stages of the experiment. The calculi are composed chiefly of calcium phosphate.

- 2 Addition of vitamin A causes disintegration and solution of the calculi experimentally produced in rats.

- 3 The chemical conditions necessary for the formation of calculi are produced by vitamin A deficiency.

- 4 An acid ash diet high in vitamins, especially vitamin A, is suggested as a prophylactic measure to prevent the recurrence of calculi in patients who have had urinary lithiasis, and the rôle of vitamin A in the diet to prevent primary calculous disease is important.

- 5 A high vitamin acid ash diet has produced a decrease in the size or total disappearance of renal calculi in patients refusing surgical intervention or in whom operation has not seemed indicated. In eighteen collected cases in which the high vitamin, acid ash diet has been used the renal calculi have undergone solution, according to roentgenographic evidence.

FIG. 3.—A kidneys, ureters and bladder of a woman aged 51 showing bilateral renal calculi. B roentgen examination eleven months later showed decrease in large renal calculi in the right kidney. The patient has passed approximately 200 small stones.

patients, multiple large bilateral renal calculi have decreased definitely in size within thirteen months. One of these patients never had passed sand or calculi in the urine until she had been taking the special diet for three months and the urine is now continually loaded with sediment and small stones (fig 3). Another patient had a large silent stone completely filling the left kidney. Operation was refused and, after the patient had taken the high vitamin diet for six months

ABSTRACT OF DISCUSSION

DR VINCENT J. O'CONNOR, Chicago: Much has been learned about the etiology of urinary stone. Keyser, among others, has pointed out the importance of metabolic influences. The disturbance of calcium and phosphorus metabolism associated with parathyroid adenoma has been emphasized by the Massachusetts General Hospital group this year. Holmes and Coplan showed the relation of excessive alkaline ash and acid ash diets in the etiology of urinary calculi. I have been tabulating the frequency of renal stone formation in patients who have observed a prolonged alkaline management for gastric and duodenal ulcer. This study covers a period of more than

fourteen years and comprises some sixty individuals. The persistent low grade alkalosis with alkaline urine seems to be the etiologic factor in the formation of small white crystalline calculi in these ulcer patients. The stones are composed almost entirely of calcium carbonate, an uncommon stone in the records of large series of analyses. Since the original presentation of Dr. Higgins's work two years ago, I have utilized his ideas clinically by having patients on alkaline powder treatment take halibut or cod liver oil in large doses. Several patients who had recurrent stones several times each year for several years (one had passed thirty stones in six years and all of them pure calcium carbonate) have had no evidence of stone during these two years although being obliged to continue their ulcer management. An attempt should be made to institute a regimen for the prevention of recurrence. This includes not only the elimination of systemic focal infection, the correction of defective urinary tract drainage and the clearing up of urinary infection but also the determination as to whether or not in a given individual the stone is the result of an excessive acid or alkaline ash diet. The analyses of the calculi help greatly in this as does a study of the reaction of the urine when the patient is on various dietary managements. Clinical experience shows that the average physician advises every patient with urinary lithiasis to avoid meat eggs and fats. In the case of the many patients who are forming stones in an alkaline urine these are the foods they need most. The work of Dr. Higgins accentuates that from a metabolic point of view the dietary correction varies with the individual depending on whether he is forming stones as a result of excess acid or alkaline ash. It is obviously as wrong to prescribe excessive vitamin A food in an individual forming acid ash stones as it is to alkalinize a patient further whose dietary ash residue is alkaline. The haphazard prescribing of excessive amounts of citrus fruit juices and prolonged ingestion of alkalis is not an aid to metabolic problems unless it is based on a careful study of the requirements for each individual under consideration.

RECURRENT UROLITHIASIS ETIOLOGIC FACTORS AND CLINICAL MANAGEMENT

LINWOOD D. KEYSER, M.D.

ROANOKE, VA.

While the etiology of urolithiasis is far from clear, an attempt may be made at correlation of data from laboratory and clinical sources with an effort to ascertain what facts may be of value in the preventive therapy of recurrence.

Experimentally the production of calculi in laboratory animals may be recounted in the following ways:

- 1 By the feeding of oxamide
- 2 By producing an artificial excessive excretion of calcium oxalate.
- 3 By excessive doses of parathyroid extract and of viosterol
- 4 The formation of uric acid calculi in animals with Eck fistulas
- 5 By feeding diets deficient in vitamin A
- 6 By infection with urea splitting streptococci, staphylococci and *B. proteus-ammoniae*
- 7 By the incrustation of organic or inorganic foreign bodies in the presence of infection

The first four of these methods imply an aseptic metabolic disturbance associated with excessive excretion of urinary crystalloids. The role of infection in the sixth and seventh method of experimental calculus production is obvious. That the infection is specific is attested by the fact that organisms successfully used by different observers were isolated from the teeth, tonsils or urine of patients afflicted with active stone

formation and that the use of strains of similar organisms from other sources gave negative results.

The mechanism of hyperexcretory calculosis (figs 1 and 2) has been dealt with in numerous reports.¹ This mechanism takes one at once to the realm of physical chemistry. Lichtwitz² and Schade³ have shown that the water insoluble constituents of stones (crystalloids) are held in a state of dispersion in the urine by adsorption to irreversible urinary protective colloids. In experimental animals I showed that an increased excretion of calcium oxalate resulted in first a precipitation of isolated octahedral, dumb-bell or tabloid crystals but that further intensification of the excretion of oxalate resulted in an inadequacy of the colloidal mechanism to maintain either solution or deposition of isolated crystals. In consequence, fusing clusters of coalescent spheroidal crystals were precipitated and stone formation took place (figs 3 and 4). Especially in the case of oxamide calculosis pigment and organic matter, probably the gel of the irreversible colloid, accompanied the deposition of stone forming spherules and served to form the organic framework of the stone.

The mechanism of infectious calculosis is not so clearly demonstrable. Hager and Magath⁴ felt that *Proteus ammoniae* formed calculi in bladders previously irritated by salicylic acid, through the process of splitting urea and depositing precipitates of magnesium ammonium phosphate and calcium carbonate on abraded mucous membranes. These precipitates tended to break off and form free calculi in the bladder. Likewise, in experimental streptococcal calculosis in rabbits (figs 5 and 6), I have shown the initial lesion to be an impregnation of lime salts in necrobiotic cells of the mucosa. From this incrustated cystitis, free particles break away to grow as calculi. In one instance this process was most intensive even in the kidney pelvis and ureters. Thus from the experimental standpoint infectious calculosis seems related more to the deposition of lime salts in tissues, a process the chemistry of which has been much studied, with varying and somewhat conflicting opinions.

Vitamin A deficiency lithiasis has provoked much speculation. As a cause of stone, vitamin deficiency has been championed by the English school and in America Higgins⁵ has presented evidence of its etiology bearing on the disease. His observation that calculosis begins in rats before the advent of infection is illuminating. While I am hesitant to disagree with those who hold for a vitamin factor in lithiasis, a general survey of the subject reveals some points that I cannot rationalize with certain clinical facts.

In the first place, this type of stone formation has been noted chiefly in rats, a species rather remote phylogenetically from human beings. The occurrence of urolithiasis is a late stage in a progressive state of malnutrition, other prominent and concomitant features of this malnutrition being biliary calculi, cachexia and

changes in the cornea, in the retina, and in the respiratory and alimentary tracts. These concomitant features of experimental avitaminosis stone are certainly not common or even infrequent accompaniments of calculous disease as it is seen in America. Even children in whom the formation of stone is somewhat rare seldom present calculi and the general malnutritional changes associated with marked vitamin deficiency.

Furthermore, in the pathologic study of the urinary tract, keratinization of the epithelium is not a common finding with stone. Vesical calculus in boys in certain geographic areas as Rumania, Dalmatia, the Canton province and the Indian Punjab does seem to be related to a cereal diet deficient in vitamin A. However, children who are fed on a similar diet in other contiguous areas are singularly free from stone. The factors of infection and of excessive crystalline excretion are yet to be ascertained in this type of stone disease.

Since 1920 when I first began the intensive study of urolithiasis I have had an opportunity to investigate personally several hundred patients afflicted with urinary stone in its various phases. In each instance a searching inquiry into the previous dietary has led to not a single striking case of vitamin or nutritional inadequacy. Many of these patients who had recurrent stone had at some time lived largely on a diet of milk, eggs, fruit and vegetables, which while adequate in vitamin content, did produce an alkaline urine of more or less intense degree. Milk alone seemed to aggravate the process in certain instances. This is significant in that milk while rich in vitamins, furnishes an abundance of calcium and phosphorus and is a producer of alkaline urine. Certainly there is much to be learned before a vitamin deficient diet can be accepted as a cause of stone in the usual American patient.

Whether the urinary colloids may, under certain metabolic conditions, become inadequate to hold the normal amounts of crystalloids present in the daily urine output in solution and whether in consequence

Fig. 1—Hyperexcretory calculosis in a rabbit fed oxamide daily for seventeen days.

of this stone may arise are possibilities concerning which there are no available data. The occasional occurrence of fibrin phosphatic stone is suggestive that fibrinogen, an abnormal colloid, may at times find entrance to the urinary stream and, in being precipitated to fibrin, be associated with calculus formation.

From the clinical side, evidence for the two types of calculosis, namely, hyperexcretory and infectious, is abundant. Uratic calculi are known to be associated with hyperexcretion of uric acid, cystine calculi with the abnormal appearance of a crystalloid foreign to the urinary tract. Recently the high incidence of cal-

cium phosphate calculus in hyperparathyroidism has been noted by Barr, Bulger and Dixon⁶ and in an especially interesting group of cases from the Massachusetts General Hospital by Churchill and Cope⁷ and by Albright, Aub and Bauer.⁸ Hypercalcemia, hypophosphatemia, hypercalciuria and hyperphosphatemia, associated with excessive secretion of parathyroid extract follows clinically an almost identical course

Fig. 2—Hyperexcretory calculosis. Calcium oxalate stones in rabbit's bladder. Result of intense oxaluria produced by injection of N-butyl oxalate and calcium chloride.

with that which I have noted with intense calcium oxalate hyperexcretion in the experimental animal. Excessive crystalline material is excreted, even the renal tubules being clogged with lime salts. This phenomenon was likewise noted with artificial oxalate stone (fig. 4). Certainly hyperexcretory calculosis is approaching the point of establishment as a clinical entity, the chemistry of the stone with concomitant studies of the urine and blood leading to its possible diagnostic recognition.

Likewise the clinical evidence for calculosis from infection with alkaline urea splitting specific streptococci, staphylococci and Proteus organisms is abundant. The works of Rovsing,⁹ Hryntschak,¹⁰ Hellström,¹¹ Hyman,¹² Cifuentes,¹³ Legueu and Coidan,¹⁴ Lau¹⁵ and

others have shown the consistent association of stone forming pyelonephritis with bacterial infection

From such a survey I feel that experimental evidence is now sufficiently correlated with clinical data to justify the acceptance of at least two mechanisms of stone formation as reasonably well established facts, first metabolic hyperexcretion of crystalloids and second infection with biologically specific stone forming bacteria. The first mechanism will produce stones corresponding largely to Albarran's primary calculi and the latter to secondary calculi of earthy phosphates and carbonates. Doubtless other mechanisms will also be shown to be at fault each of them acting in some way to upset the solvent properties of the urinary colloids.

CHARACTERS OF RECURRENT CALCULI

The recurrence of calculosis following the removal of stone is estimated at from 4 to 25 per cent varying with the series of cases reported. Judd and Scholl¹⁶ and Braasch and Foulds¹⁷ estimated 10.3 per cent recurrence in 1413 cases of renal calculus. 11.8 per cent recurred following pyelolithotomy and 24.3 per cent following nephrolithotomy. Small stones are more likely to be associated with recurrence than larger calculi. Branched stones seem more prone to recurrence than smoother varieties.

Certain individuals seem to be possessed of what may be termed "stone forming kidneys." Their calculi may recur at the same site or at different parts of the urinary tract, first one side being involved and then the other. The removal of calculi is only the starting point for a renewal of the stone forming process.

The most rapid stone formers are those with recurrent ureteral calculi, these probably arising in the kidney above. Another perhaps smaller group tend to confine calculosis to the kidneys and suffer repeated surgical removal of stones at intervals of from months to years. Recurrent vesical calculus is less frequent in incidence. As a rule recurrent concretions are chemically distinct

Fig 3—Hyperexcretory calculosis. Small calcium oxalate calculi experimentally produced and crushed on a slide to show crystalline elements in structure. The small fusing spheroids constitute the structural units.

and not mixed varieties and are of the same composition as their predecessors. Most frequently associated with recurrence are phosphates and carbonates. These are most often found associated with infection of coccic or bacillary type and are the variety most often noted with uroastasis, such as vesical neck obstruction, hydro-ureter, hydronephrosis, ectopic kidneys and the like. There is no definite evidence, clinical or experimental, that

urostasis alone will initiate stone formation, but uroastasis does invite and maintain the existence of infection, and when this is a stone forming infection uroastasis, by producing urinary stagnation, will produce rapidity of growth.

On the other hand the evidence for recurrent aseptic calculus of the hyperexcretory type is being more frequently recognized as in the case of cystine and uratic

Fig 4—Hyperexcretory calculosis. Oxalate deposits in renal tubules associated with chemical nephritis. A consistent finding in experimental oxalate lithiasis.

calculi and more recently the calcium phosphate stones of hyperparathyroidism already mentioned. Just how often this type of calculus reforms is a question that one must wait for clinical investigation, probably in the near future, to answer.

MEASURES EMPLOYED IN PREVENTIVE THERAPY AGAINST RECURRENCE

Preventive measures against recurrence should be started with the removal of all stones as far as practicable by surgery or cystoscopy. At operation fluoroscopy or immediate kidney roentgenograms should be used, and the avoidance of exposure of suture material to the urinary stream and the insurance of proper urinary drainage should be practiced. In badly infected calculous pyonephrosis the utilization of nephrostomy as developed recently by Cabot is of value.

An immediate qualitative chemical examination of the calculus obtained should be made. A quantitative examination of the various constituents would be ideal but is hardly to be afforded by the average clinical laboratory. As urologic textbooks and manuals of laboratory technic seldom give definite directions for the analysis of calculi, I have modified an outline from two standard works on physiologic chemistry which can be carried out in any clinical laboratory and which has proved of value in my own experience. It is reproduced here in the accompanying table.

Repeated roentgenograms immediately and at periods of from six months to one year should be practiced. A careful study of the patient's metabolism should be carried out with every feature of laboratory diagnosis available. The blood uric acid and now the serum calcium and serum phosphorus seem to be additional data that should be secured as a routine and repeatedly, if one is properly to evaluate the incidence of hyperexcretory calculosis. If hyperparathyroidism is suggested, roentgenograms of the bones and other data pertinent to this disease should be determined.

Dietary regulation¹⁸ with regard to the intake of purines, oxalates or calcium and phosphorus is indicated

A Chemical analysis of stone removed

A SIMPLE METHOD FOR THE QUALITATIVE ANALYSIS OF URINARY CALCULI

(Modified from Hawk and Bergelm—Physiologic Chemistry and Hammarsten Lehrbuch der physiologischen Chemie)

Each of the concentric layers of the calculus must be subjected to separate analysis. Material for examination is obtained by sawing the calculus carefully through the nucleus then separating the layers or by scraping off from each layer (without separating the layers) enough powder to conduct the examination as outlined below

On heating the powder on platinum foil it	Does burn	Without flame	the powder gives the murexide test *	The powder when treated with KOH gives	No noticeable ammonia reaction	Uric acid
		With flame			Strong ammonia reaction	Ammonium urate
	Does not burn	The powder when treated with HCl	Does not effervesce	The powder gently heated then treated with HCl	Effervesces	Calcium carbonate
						Calcium oxalate
						Bone-earth (magnesium and calcium phosphate)
On heating the powder on platinum foil it	Does not burn	The powder when treated with HCl	Does not effervesce	The powder gently heated then treated with HCl	Effervesces	Triple phosphate (mixed with unknown amount of earthy phosphate)

* Murexide test. To a small amount of the powder in a small evaporating dish add 2 or 3 drops of concentrated nitric acid. Evaporate to dryness over a very low flame. A red or yellowish residue remains which turns purplish red after cooling the dish and adding a few drops of very dilute ammonium hydroxide. The color is due to the formation of murexide.

Blood chemistry studies—

Blood uric acid—serum calcium—serum phosphorus

B Uratic calculi—Low purine diet—

Intense alkalinization of urine

Calcium oxalate calculi—

Low oxalate dietary *

Intense acidification of urine (pH 4.5) (calcium oxalate is precipitated in wide range of urinary reaction)

Calcium and ammonium magnesium carbonate and phosphate calculi—

Low phosphate dietary *

Intense acidification of urine (pH 4.5)

Cystine calculi—

Intense alkalinization of urine

C To acidify urine—ACID ASH DIET—

Bacon

Bread white

Bread whole wheat

Cheese

Corn

Crackers

Cranberries

Creosol whole

Egg

Fish

Salmon

Ment

Outmeal

Oysters

Peanuts

Prunes

Rice

Sardines

Shredded wheat

Walnuts

Dilute nitrohydrochloric acid (aqua regia)

Conc. nitrohydrochloric acid

Distilled water q. s.

Take 1 dram in 1 glass water every one to two hours to tolerance. Sip through tube and raise mouth with

sodium bicarbonate solution after taking

Ammonium chloride—6 to 10 Gm. daily—enteric coated tablets } Watch stool to be sure enteric coated tablets are absorbed

Ammonium nitrate—6 to 10 Gm. daily—enteric coated tablets } If not use drugs in suitable liquid vehicle

D To alkalinize urine—ALKALINE ASH DIET—

Almonds

Apples

Asparagus

Bananas

Beans

Beets

Cabbage

Carrots

Caulliflower

Celery

Chestnuts

Cocoanut

Cucumbers

Currants dried

Lemons

Lettuce

Milk whole

Molasses

Mushrooms

Melons

Onions

Oranges

Peaches

Pears

Peas

Potatoes sweet

Potatoes white

Radishes

Rutabagas

Turnips

Magnesia potassium citrate or acetate sodium bicarbonate

E To Treat the Urinary Tract Infection—

Cultures at initial urologic examination

Ketogenic diet for bacillary infection (A. L. Clark J. Urology 31:193 [Feb] 1934)

Methenamine—keep urinary reaction below pH 5.6 Acetarsophenamide for acute infections

Reduce focal infections—teeth—tonsils—prostate—cervix—alimentary tract

Surgical drainage or periodic cystoscopic lavage with a view to correcting urosteriasis

Lavage with 1 to 2 per cent phosphoric acid or maleic acid may aid in dissolving concretions or minute fragments

Start with weaker solutions to test tolerance of patient

F Increase Vitamin A Intake—

Sources—Cod liver oil—halibut oil—Carotene oil (provitamin A or carotene)

Foods—

Milk

Butter

Cheese

Eggs

Vegetables with green

or yellow pigment

Tomatoes

Bananas

Oranges

Peaches

Pineapples

Prunes

* An excellent series of diets are listed in an article by Grant and Simpson South M J 23:628 (July) 1930

† Maleic acid (inactive)—A. H. Thomas Company Philadelphia

according to the predominant chemical found in the chemical analysis of the calculus. A high intake of vitamin A should receive further clinical trial as first suggested by Keenins and Turkeltaub. I have used vitamin A drugs and diet as a routine procedure during the last four years.

Fig 5—Infectious calculosis produced by infection of rabbit's bladder with streptococci from the urine of a stone forming patient. Note encrusted cystitis, dilated ureters and pyonephrosis five weeks after infection.

After every effort has been made to correct the metabolic disturbance present, an intensive and persistent effort to eradicate or to reduce to a minimum the infection should be made. Initial and repeated bacteriologic studies of the urine are imperative. The role of focal infection is not clear. Just why teeth infected with streptococci should produce a stone-forming infection when *Proteus*, colon bacilli or staphylococci are found in the urine is difficult to explain, unless one considers the latter organisms secondary invaders. I agree with Hunner¹⁹ that the chief object of attack is urosthesis, and I practice periodic postoperative lavage as a routine with the free use of indwelling catheters and ureteral dilation of bulbs up to 16 F. In spite of sharp controversy concerning this procedure, I feel that it is one of the best therapeutic measures in treating any type of chronic nontuberculous urinary infection. Antiseptic drugs may aid, especially methenamine if the p_H is kept below 5.6. Neosarsphenamine in certain instances of coccic infection may be tried at times with success.

Finally, the reaction of the urine should be shifted to the opposite of that which is ideal for deposition of the stone. This will mean intense acidification of the urine in the case of oxalatic, carbonate and phosphate calculi, while alkalization will be indicated with uratic and cystine varieties. The urinary reaction should be

made in terms of the hydrogen ion concentration, numerous small determinators such as the one put out by the LaMotte Company being available for office use. If such apparatus is not at hand, the use of methyl red paper as an indicator is of value.

The hydrogen ion concentration of the urine is a great factor in aiding the urinary colloids to maintain solution. That acid urines are clear and alkaline urines are clouded with phosphates and carbonates is a matter of common knowledge, and each chemical constituent of stone has its ideal range for crystalline precipitation. In maintaining an intense acidity ammonium nitrate and chloride dilute aqua regia, and the ketogenic or an acid ash diet are available and usually will bring the urinary reaction to a point below p_H 5, this being only slightly influenced by the morning alkaline tide and that following ingestion of food. A diet rich in acid ash may be used if this does not interfere with other dietary considerations already mentioned. The ketogenic diet affords in addition to its urinary acidifying properties the best antiseptic for bacilluria, as has been demonstrated by Helmholtz and Clark.²⁰ In many cases it acts almost as a specific for this type of infection and with acidifying drugs pushed to the point of gastro-intestinal tolerance will possibly dissolve crystalline material and minute fragments. The coccic infections are most persistent and respond poorly to any treatment with which I am familiar. Neosarsphenamine intravenously will occasionally give a brilliant result.

Fig 6—Infectious calculosis produced by instillation of streptococci from the urine of a patient with a stone-forming kidney four weeks after infection. The process appears to start with a deposition of lime salts in necrobiotic epithelium.

On such a basis I have treated seventeen cases of recurrent calculosis, sixteen of which I reported in detail last year. The seventeenth case, a patient with recurrent phosphatic ureteral calculi, has been free from stone now for one year and may be added to the group.

¹⁹ Hunner G. L. Calculus of the Upper Urinary Tract with Special Consideration of Recurring Stone Formation. *Tr. Western Branch American Urological Association* 2: 65-87. 1933.

²⁰ Clark A. L. The Ketogenic Diet in the Treatment of Urinary Infections. *J. Urol.* 31: 193-205 (Feb.) 1934.

These patients presented the syndrome of recurrent calculosis in intense degree and the cycle of their recurrence has been definitely broken for periods of from one to nine years. None of the seventeen have had a recurrence during the past year. Eleven are absolutely free from pus and bacteria in the urine. A minor degree of infection persists in six. Whether these results can be repeated and maintained in a larger series of cases remains for the future to show, I feel, however, that this type of clinical management sets a precedent in breaking the cycle of recurrent stone which has not hitherto been attained.

THE POSSIBILITY OF DISSOLUTION OF CALCULI

Recently interest has been revived in the possibility of dissolution of calculi. Randall's²¹ introduction of phosphoric acid in the treatment of incrustations and of small fragments is noteworthy and a distinct contribution to the subject. My own experience with phosphoric acid in solution of from 1 to 2 per cent has not been encouraging as I have had several severe reactions from renal lavage with this drug.

During the past year I have studied the solution of stones of the phosphatic and the carbonate type in

Fig 7—Large carbonatic calculous pyonephrosis in right kidney treated by nephrectomy. Recurrence in left kidney after thirty days. Streptococcal infection. Reduction in size of calculous mass with two small fragments remaining after thirty days of urinary acidification and pelvic lavage with phosphoric acid.

the test tube with a series of weak organic acids. These included tartaric, lactic, malic, citric, acetic and trichloroacetic acids in various combinations. A study of the solvent action of caroid, pepsin and urea alone and in combination with these acids in dilutions of from 1 to 3 per cent has also been made. While these studies are to be reported elsewhere, I may say briefly that all these acids exert a moderate solvent action at incubator temperature. Much depends on the density of the stone, however. The outer layers dissolve as a rule rather rapidly, but as the inner layers and nucleus are approached one reaches a point at which dissolution is much delayed or brought to a standstill. One phosphatic calculus of 2,800 mg. was reduced to 1,800 mg. in twenty-four hours with a mixture of tartaric, malic and lactic acids, each in 1 per cent strength. Within wide limits not so much seems to depend on the acid used as on the density or compactness of the calculus.

Clinically it is difficult to apply acid solutions to the surface of calculi for any length of time by catheter irrigation. Continuous irrigation with phosphoric and malic acids has resulted after a short time in ureteral or vesical spasm which becomes intolerable to the patient and invites a severe inflammatory reaction. Malic acid has been used satisfactorily in strengths of

from 1 to 3 per cent in dissolving phosphatic incrustations and seems less irritating than phosphoric acid of similar strength and is, to my mind at present, the acid of choice. By mouth, Wise²² found malic acid to be nontoxic in dogs and to be excreted from 20 to 40 per cent unchanged in the urine. In doses of from 8 to 16 mg. daily it is not, however, a good urinary acidifier, as the amount of alkali carried through from neutralization in the intestine tends to offset the acid portion that is excreted unchanged.

To Crowell²³ is acknowledged the distinction of first dissolving urinary calculi by purposive therapeutic means. In dealing with recurrent cystine calculi, he caused their dissolution by intense urinary alkalization and renal lavage with alkaline drugs.

Three cases of partial or complete solution of stone in situ have been noted in my own experience, setting a precedent in the purposive dissolution of alkaline earth calculi. In the first, a woman suffered a marked recurrence of carbonate stones in a previously stone free and uninfected left kidney, three weeks after right nephrectomy for calculous pyonephrosis (fig 7). The urine, which had previously been alkaline and loaded with amorphous carbonates, was acidified by dilute aqua regia, ammonium chloride and nitrate by mouth, along with an acid ash diet to p_{H} 4.5, where it was maintained over several months. Disintegration of calculi with the passage of multiple stones through the ureter ensued, with roentgen evidence of diminution of the calculous mass. A crystal clear urine was usually passed. However, two small fragments resisted ureteral dilation and lavage with 1 per cent phosphoric acid, until finally pyelolithotomy had to be done. Urinary acidification with postoperative renal lavage has been carried out over eighteen months. The patient has had no further recurrence but still presents a stone forming streptococcus in the urine that produces calculosis in experimental animals. The case is strong evidence for the prevention of recurrent alkaline earth stone by maintenance of acid urine.

A second case presented repeated recurrent phosphatic ureteral calculi of small size. Urinary acidification in a similar manner quickly brought about dissolution of a small ureteral calculus, and the patient has remained stone free over three years.

A third patient, a man aged 32, had a recurrent small phosphatic calculus in the left kidney after two years (fig 8). A stone was present at the ureteropelvic juncture. Malic acid, an acid ash diet and ammonium nitrate by mouth together with renal lavage with 2 per cent malic acid visibly reduced the stone in size roentgenographically, and after two weeks a small residual fragment was passed by way of the ureter.

Sufficient time has not elapsed and a sufficient number of cases have not been observed to furnish a positive evaluation of this treatment, but these occasional results are noteworthy and I hear of similar isolated cases from time to time. Dr. Higgins's excellent results with an acid ash high vitamin A diet are encouraging. The true significance of the vitamin A content is to my mind a matter yet to be evaluated. Progress along the line of solution of calculi is necessarily slow, and the ideal solvent has not yet been determined. However, from what has been learned of urinary calculus,

22 Wise, L. F. Elimination of Valates After Subcutaneous Injection of Sodium Valate. *J. Biol. Chem.* 28: 185 (Dec.) 1916.

21 Randall, A. Prevention of the Recurrence of Urinary Calculi. *Am. J. Surg.* 18: 482-493 (Dec.) 1932.

23 Crowell, A. J. Cystine Nephrolithiasis. Report of Case with Roentgenographic Demonstration of Disintegration of Stone by Alkalization. *Surg. Gynec. & Obst.* 38: 87-91 (Jan.) 1924.

It is possible now to make purposive efforts in the therapy of dissolution, especially in cases of bilateral alkaline earth calculi or stones in single kidneys when operation would be hazardous.

In looking to the future, one may approach the problem of urolithiasis with more confidence than has been done in the past. The hypersecretory and infectious types of lithiasis are almost certainly established as clinical entities. Research is being actively carried out to show the relationship of vitamin deficiency to the disease. A newer concept of the role of urostrasis is being brought forth. As to the reasons for form, size, rate of growth and site of calculus deposition it is necessary as yet to speculate. The conditions determining these features of calculous disease are beyond present comprehension but will doubtless be clarified when a better understanding of the physiochemical variations of this anomalous form of crystalline deposition is reached.

NOTE.—A word of warning should be given with regard to overzealous administration of urinary acidifying drugs. Occasional cases of acidosis and nephritis are noted. Hence, extreme caution should be used when the total amount of acidifying salt administered in twenty-four hours exceeds from 5 to 8 Gm. Even this dosage may be excessive if renal insufficiency is present.

Medical Arts Building

ABSTRACT OF DISCUSSION

DR. GEORGE H. EWELL, Madison, Wis. Vitamin deficiency produces marked changes in the urinary tract. Reddiwell published a paper several years ago on the possible relation of vitamin deficiency to leukoplakia and alkaline incrustation of the bladder. To my mind Reddiwell's ideas are more applicable than those of vitamin deficiency to stone formation in the human being. Osborne and Mendel clearly pointed out in their experiments that in all cases in which the rats developed calculi they were without an adequate source of the vitamin for an extended period. I cannot believe that even in these times of economic distress our patients are so lacking in vitamins as the specific diet to which these laboratory animals were subjected. Fragments of stone left at operation have been very properly stressed. Dr. Stevens showed a slide of a case in which fragments had been left for six years without any further development. It is apparent that other factors play a part. The mechanism of the production of stone by stasis and infection is not known. The hypothesis that the stone forms around bacteria and desquamated epithelium as a nidus explains the appearance of only a few stones. The hypothesis that infection upsets the colloid-crystalloid mechanism of the urine explains a greater incidence of stone as due to infection and stasis. Alkalinuria has been considered to be due to the type of infection present. Dr. Clark stated that in many of his cases of chronic urinary tract infection, in spite of large doses of acidifying drugs, he was not able to change the hydrogen ion concentration very much to the acid side. I have observed several cases of chronic urinary tract infection in which, in spite of the administration of large doses of acidifying drugs the urine remained alkaline. Those patients were subjected to gastric analyses and one patient was found to be lacking in free hydrochloric acid with a low total acidity, while the rest had marked diminution in total acidity. Their urine promptly became acid when hydrochloric acid was administered by mouth. I believe that their urinary tract infection was a part of a general disturbance in metabolism and their alkaline urine due to the hypochlorhydria and not to the type of infection that happened to be present. Two years ago before this section, I presented a paper on cystine nephrolithiasis. Cystine stones are often found in cases of recurrent urolithiasis, and cystine stones also occur in conjunction with other types of stones.

DR. FRANCIS P. TWINEM, New York. Dr. Keyser, who has been at the forefront of investigators in this problem has covered this subject in a complete manner. Decades ago Ord

showed that he could change noncoalescent calcium oxalate crystals into the coalescent form by changes in the relative proportions of colloids and crystalloids in the urine, and Shattock later showed that the coalescent variety of crystals was at the basis of calculus formation. Deficiency in vitamin A is only one factor in calculus formation. It does not explain many vagaries of geographic distribution. Dr. Keyser stated that in Punjab, India, calculosis is exceedingly common, while in other districts, in which the diet is equally deficient in vitamin A stones are rare. One geographic point that agrees with this idea however, is that investigators among the Eskimos have said that they never saw a full-blooded Eskimo with a renal calculus. However, in Iceland, among the Norwegian population in which the consumption of vitamin A is probably very high stones are common. Any theory of calculus formation should also take into consideration the fact that stones are usually found in only one kidney. About 87 per cent of cases in the series that I studied in the New York Hospital showed stones only on one side. When one considers the

Fig. 8.—Recurrent phosphatic calculus at left ureteropelvic junction. Intravenous urogram lightly retouched. Reduction in size of stone after one week of urinary acidification and lavage with malic acid. The patient passed a stone two weeks later with no other treatment.

factors of metabolic disturbances and vitamin A deficiency one would expect that these factors would apply equally to the two sides. There must be some other factor involved to account for the frequency of unilateral involvement. As to the frequency of recurrent calculi Rongiersma found nine recurrences out of sixty-one cases in aseptic stones. However in cases of infection the recurrences amounted to twenty-one out of thirty-nine cases. Rovsing found 40.3 per cent of recurrence in 109 cases. In the series of more than 200 cases that I investigated the proportion is about 15 per cent of recurrence in the aseptic or but slightly infected cases, and about 30 per cent in the cases showing infection with urea splitting organisms. Rongiersma found that, in primary nephrectomy for unilateral calculous disease recurrence occurred on the opposite side in only one case out of fifty-three. In these cases the metabolism of the individual was not changed at all, the same situation was still there as regards diet, and yet only one case out of fifty-three showed a recurrence of calculus. A large percentage of recurrence is due to wrongly preserving a badly infected kidney, a kidney infected with urea splitting organisms. I feel that a nephrostomy in an aseptic case is seldom indicated by reason of the fact that an infection nearly always supervenes. I wish to emphasize the

taking of roentgenograms on the table in cases in which there are several stones or a large, easily fragmented staghorn calculus. The analysis of the stone is important, and in my service we do this without exception. A patient whom I observed had six operations for phosphatic calculi. The urine was alkaline and was changed to acid. That patient has now gone a period of ten years without recurrence.

DR LINWOOD D. KRYSTER, Roanoke, Va. Dr Twinn has been rather insistent that there are probably a number of factors in calculus formation, and with this I agree. The attempt to centralize on one factor is likely to cause trouble. Dr Randall of Philadelphia expressed an opinion at Atlantic City which is consistent with clinical and experimental facts. He felt that there must be dissolution of the mucous membrane at some point in the urinary tract, a point of irritation or of lowered resistance before any type of calculus can take place. I have long held a similar concept of stone disease. Whatever mechanism of stone formation is at fault, whether this is impregnation of lime salts in necrobiotic tissue as in the case of artificial infectious calculus, whether it is keratinization of urinary tract epithelium as in the case of vitamin A deficiency stone, or whether it is crystalline hypersecretion, in each instance there will be some pathologic change in the epithelium that is probably essential for the process. Such a concept may explain in some measure the unilaterality or bilaterality of calculi or their formation and recurrence at specific sites.

THE MEDICAL AND SURGICAL TREATMENT OF CALCULOUS ANURIA

GEORGE F. CAHILL, M.D.
NEW YORK

Calculous anuria, the term used to denote suppression of urine due to a stone in the kidney or ureter, occurs under the following circumstances:

1 Two secreting kidneys may have both ureters or pelves blocked simultaneously, either synchronously or one following the other.

2 A single secreting kidney may be blocked, the other (a) being imperfectly developed, (b) having been destroyed by disease or (c) having been previously removed.

3 Both kidneys or a double kidney may have a fused single ureter, which may be blocked by a calculus.

4 Two kidneys apparently normal may have one kidney blocked and the other failing to secrete reflexly the so-called renorenal reflex block.

I have added twenty-two cases from the Squier Urologic Clinic to the collection of 355 cases obtained from the literature by Rubritius. On his basis of analysis these 377 cases are tabulated (table 1).

Diagnostically, in my experience, the pain and anuria have been the most important symptoms. Cystoscopy, in conjunction with retrograde injection pyelograms, was the most important diagnostic procedure. Intravenous urograms were not satisfactory. The kidneys failing to secrete the dye gave no roentgenographic shadows. In nine of the twenty-two cases, or 40 per cent, there was no calculus shadow on the roentgenogram of sufficient density to make a diagnosis.

In the treatment of calculous anuria the first step was to relieve the obstruction. The various procedures for the relief of the obstruction were:

- 1 Cystoscopy and extraction of the calculus
- 2 Insertion of a ureteral retention catheter past the obstruction with later extraction of the calculus

- 3 Ureterotomy with removal of the calculus
- 4 Pyelotomy with removal of the calculus
- 5 Nephrostomy, single or double, with or without removal of the calculus

In two cases, or 11 per cent, it was possible to use the cystoscope and extract the calculus. In one, a case in which anuria had existed for forty-eight hours without infection there was an impacted calculus in the orifice of the only functioning ureter, from which it was possible to dislodge and remove the calculus on the first examination. The second case was one of reflex or toxic anuria in which the patient had been anuric for six days, for four of which he was under treatment for circulatory collapse, with endeavors made to stimulate the unobstructed kidney. At the first cystoscopy possible to be made, the obstructing calculus in the ureteral orifice was dislodged and removed followed by rapid recovery of the patient. This procedure, when it can be performed, offers the shortest method of relief. One additional case presented an anuria of two stages. The first stage was an anuria of two days from a block of the only kidney, with relief on the passage of the calculus into the bladder, only to become lodged in the urethra totally obstructing it. The calculus was removed from the urethra with a Howard spiral stone dislodger.

In three cases, or 14 per cent, it was possible to pass a ureteral catheter by an obstructing calculus in the ureter of a solitary kidney. Two of these calculi were in the lower ureter and one in the upper ureter. All were uninfected and the two in the lower ureter were primary calculi. The catheters were left in place to drain the kidney, which they did successfully. In the two lower ureteral calculi, on removal of the catheter after twenty-four hours had elapsed, the calculi were successfully passed and to date there has been no recurrence. In the case with calculus in the upper ureter the catheter dislodged the calculus back up the ureter, leaving the kidney unblocked. This case, one of cystine stone, showed a rapid increase in size of the calculus and a descent seventeen days later with recurrence of the anuria necessitating a ureterotomy for relief. To date there has been no recurrence of calculus. In several other cases it was possible after considerable manipulation to pass a small catheter by the obstructing calculus but no therapeutic value could be obtained by the use of the catheter because these cases were associated with infection and drainage was effected through the catheters with difficulty. Eisen-drath reported good results in catheter drainage of some anuric patients, and it may be of benefit in the preparation of these cases for operation to lessen the risk.

Ureterotomy with removal of bilateral calculus was done in two cases or 10 per cent. One presented bilateral calculi in the lower ureter with a four day anuria and infection. Drainage was attempted by cystoscopy and catheter without success. The calculi were removed by a midline bilateral pelvic ureterotomy, followed by drainage. The operation was followed by paralytic ileus, septicemia and death. The second case presented a pyelolithotomy with decapsulation of one kidney for a calculus obstructing the pelvis and a ureterotomy with removal of a calculus from the lower ureter on the opposite side. This case was of long standing anuria with infection and the operative procedure was followed by septicemia, exhaustion and

death. Autopsy showed a perinephric abscess and multiple abscesses throughout the parenchyma of the untouched kidney, unrecognized clinically because of stupor and toxemia.

Experience with these two cases, in contrast to the three similar cases in which the calculus was ignored at first and a nephrostomy with renal decapsulation performed, all three followed by recovery, confirms the

belief based on experience and previously expressed in my reported cases, as well as the belief of other writers, that, when anuria is severe or associated with infection, drainage is the safer procedure. Removal of the calculi would seem to be the first necessary step, but the risk of having unrecognized renal damage or infection that is masked by the toxemia is too great. Nephrostomy with drainage in this type of case is better surgery.

Pyelotomy or ureterotomy near the pelvis with removal of the calculus was done in four cases, or 18 per cent. In all these, the kidney had not been previously operated on and they were all classified as uninfected. In all, the renal area was exposed and the kidney freed and examined. The renal fossa was drained to care for the perirenal edema. Recovery was rapid in these four cases and to date there has been no recurrence. Technically the procedure was simple except for the marked edema of the perirenal tissues obscuring the field, and they were all practically bloodless.

A combination of pyelotomy and nephrostomy was done in three cases or 13 per cent. These were all recurrent calculi and in all there was a clinical evidence of infection. The cases presented multiple calculi in addition to the obstructing ones. The calculi were removed from the kidneys through the pyelotomy incisions, but the nephrostomies were done for better drainage, for longer drainage and for intrarenal lavage. Two of these patients had a recurrence of calculi with

15th day	Urea	21 mg	per hundred cubic centimeters

anuria. In both cases, drainage by nephrostomy was again done. The infection in each persisted in spite of drainage, lavage and medication, accompanied by slow deterioration of renal tissue. Death finally resulted from exhaustion and infection. One patient has continued on drainage with a functioning kidney but with persistent renal infection. This is apparently made worse by intrarenal lavage and progresses satisfactorily without it.

Nephrostomy was done in eight cases, or 36 per cent. Of these, three were cases of calculi in kidneys not

previously operated on. In these three cases, the calculus in the ureter was ignored at the time of nephrostomy, and in two the calculi were passed spontaneously while the nephrostomy was draining. The third necessitated a ureterotomy and removal of the calculus while the nephrostomy was draining. None of the patients were considered to be infected clinically. All have been well to date—two for six years and one for three years. Four patients had calculi in the kidneys not previously operated on, but in all evidence of severe infection was present. Of these, one recovered from a toxic suppression or a renoreflex suppression and has been alive seven years without recurrence. Two patients were seen in the terminal stages of obstruction and they failed to survive the nephrostomy. In the last of these four cases, nephrostomy was performed three times for anuria with infection and recurrent calculi. The last nephrostomy was made permanent and the patient survived three months. Autopsy showed that the kidney had developed a thick inflammatory exudate covering the entire pelvis and calices and obstructing all the collecting tubules. One of these eight patients had two attacks of anuria, both relieved by nephros-

tomy. Under treatment he has been well and free from recurrence for eight years.

In cases of bilateral obstructions, the operation on both sides was done at one sitting. The last obstructed kidney was always operated on first. This was done on the supposition that this kidney would be the least damaged and, if any operative accident prevented the relief of the second kidney, temporary function at least would be restored.

Following relief from obstruction there were marked changes in the patient's symptoms. Before operation the patient usually showed a dry skin and lack of thirst, after operation there was profuse sweating and return of thirst. In the uninfected cases there was rapid secretion of urine and the elimination of the increased urea retention from the blood, for example, uninfected block with recovery (table 2).

In the infected cases secretion often did not start until twenty-four or forty-eight hours or more after the nephrostomy. It was assumed that it was necessary for the renal tissue to be relieved of the edema and infectious tissue exudate before its proper physiologic function could be resumed. In all these cases the blood urea increased for a variable time usually several days, before beginning to fall. The fall was then at a regular rate, for example a case, infected, with three days anuria (table 3).

tion of urinary salts C H Mayo⁴ often has directed our attention to the question of stagnation and infection, and he regards the kidney as an organ of filtration which is constantly eliminating bacteria from the circulation This hypothesis of infection he considers the only tenable one, and he contends that the development of stones requires the presence of two types of bacteria, one of these produces hematogenous infection, whereas the other may come from a local focus Bacteria of the stone-forming type must come in contact with the mucoid exudate when the latter is present in the kidney as a result of the first infection Rovsing⁵ expressed the opinion that urea-splitting organisms account for 71 per cent of the recurrences of stone, and that nephrectomy should seriously be considered in renal lithiasis when a urea-splitting organism is found unilaterally This seems to us in view of present methods of postoperative care a radical procedure and not justified

There is no doubt that stasis and infection are contributory causes in many cases of nephrolithiasis, but the exact influence these factors exert is not clear The frequency of formation of stone associated with obstruction of the urethra and of the vesical neck, with diverticula of the bladder, and with incomplete obstruction at the ureteropelvic juncture certainly is presumptive evidence of the etiologic influence of faulty drainage in cases of renal lithiasis Infection is associated with faulty drainage in most instances Livermore⁶ and others hold that it is only of academic interest how the infection gets into the urinary tract, whether by way of the blood stream or by stasis from ureteral stricture, ptosis of the kidney, tumors of the kidney, faulty metabolism or dietary indiscretion, any of these may cause sufficient irritation to the renal pelvis to allow infection to gain a foothold and to furnish the nucleus of blood or pus on which crystals may deposit Hunner⁷ and Mathe⁸ regard ureteral stricture as an important factor in the cause of formation of stone That this theory is difficult to prove has been pointed out by Braasch⁹ in that it is quite as difficult to say whether stricture found at operation is primary or secondary as it is to determine its presence clinically In addition, renal or ureteral stone is so often found without any evidence of stricture that it can hardly be a common etiologic factor

Keyser¹⁰ is of the opinion that there is sufficient clinical evidence to show that stasis is not the primary factor Stirling¹¹ in discussing renal stones, noted their presence in only 15 per cent of cases of prostatic obstruction, and he found that vesical diverticula, ureteral strictures hydronephrosis, ulcerations of the bladder and infections of the urinary tract without stasis, in general are more often found without calculus than with it He expressed the opinion, however, that when the stone-forming mechanism is present, when crystals are being deposited by infection or by colloidal

disturbances, it can easily be understood how stagnation enhances their retention and growth

DIETETIC FACTORS CAUSING STONE

Careful study of the experimental work of McCarrison¹² on the formation of renal stones in rats and cattle in India, and his clinical observations on this disease among the various peoples of India, leaves no doubt that there is some evidence of a relationship between a deficiency of vitamin A and the formation of urinary calculi Furthermore McCarrison noted that, if vitamin C was removed from the diet along with vitamin A, a greater influence on stone formation was produced and if earthy phosphates were added to this diet deficient in vitamins, the rate and degree of calculus formation was increased The mechanism involved is not settled, but a fairly clear explanation is the serious injury that occurs to the urinary epithelium in the presence of a deficiency of vitamin A It is quite probable that the desquamated, keratinized epithelium from the urinary tract may form the nidus around which deposition of stony material occurs The stones produced experimentally nearly always are of the calcium phosphate variety The interesting point in this connection is that they are nearly always associated with infection Joly regards the formation of stone following a deficiency in vitamin A as resulting from some action on the urinary colloids that reduces their power of holding stone-forming salts in solution

THE ROLE OF PROTECTIVE COLLOIDS

Ebstein¹³ was the first to draw attention to the importance of the colloids in stone formation, and he was of the opinion that colloids were the primary factor and crystalloids the secondary factor in their production Rainey and Ord,¹⁴ however, previously had pointed out that crystals formed in solutions containing colloids differed from those derived from pure watery solutions From the work of Ord and Shattock,¹⁵ who laid down the physical principle that colloidal matter in vitro modified crystalline morphology, and from the microscopic studies of oxalate and urate calculi by Ord,¹⁶ who concluded that they were made up of a variety of fused crystals, it appears that the power of the urine to hold the water-insoluble salts of stone in solution is due to protective colloids These physical principles have been confirmed by Lichtwitz¹⁷ and Schade¹⁸ Joly expressed the belief that, in general, both crystalloids and colloids are essential in the production of stone and that it is incorrect to assign a principal part to either of them, too, that this is the generally accepted opinion

Keyser has caused calculi to be formed in the urinary tract by producing excessive excretion of urinary crystalloids in such an amount that the protective colloids could no longer take care of the solution of the crystals

These observations indicate that the prevention of calculi is dependent on protective colloids in the urine

When crystalloids are abnormally excessive, colloids may be unable to retain them in solution thereby resulting in formation of calculi. Likewise if the protective power of the colloids is interfered with, as Keiser stated, by the production of abnormal colloids that may arise from metabolic sources or from the product of bacterial inflammation, then calculus formation may result.

HYPERTHYROIDISM

Studies on the parathyroid bodies recently have served to increase the probability that renal lithiasis is in some fashion linked to disturbances in metabolism. Albright, Aub and Bauer¹⁸ relate that hyperparathyroidism is almost unique in giving the combination of a high level of serum calcium and of a low level of serum phosphorus which is accounted for by an increased production of the hormone of the parathyroid bodies which in turn produces a disturbance in the metabolism of calcium and phosphorus. The manifestation of this metabolic disturbance also is revealed by an increase of both calcium and phosphorus in the urine. Polyuria and polydipsia are noted in nearly all cases and are attributed to the increased excretion of calcium and phosphorus. A similar observation was made by McCarrison in his feeding experiments on rats. This increase of calcium and phosphorus in the urine may lead to the formation of urinary calculi. Albright and Baird¹⁹ found twenty-three instances of this in a series of eighty-three cases. Moreover, the calcium phosphate was deposited in the parenchyma of the kidney, so that the renal pyramids were sometimes outlined by a flat roentgenogram of the abdomen. Of seventeen cases of hyperparathyroidism reported by Albright, Aub and Bauer, in ten urinary calculi were present, whereas in seven the only symptoms were those pertaining to calculi and in five of these seven there were no evidences of bone disease. This observation seems to us important, if one is seriously to consider disturbance in metabolism as an etiologic factor in the production of renal stones. Eight of these seventeen cases of hyperparathyroidism were discovered as a result of doing routine calcium and phosphorus determinations on all patients with urinary calculi. Albright and his associates were inclined to deduce from the foregoing evidence in their group of cases that hyperparathyroidism will turn out to be a fairly common cause of urinary stone.

Dysfunction of the parathyroid bodies is now definitely associated with a rather high incidence of renal lithiasis, which is fundamentally the result of disturbed calcium and phosphorus metabolism. It is not unlikely that urinary stones associated with long disability incident to fractures, arthritis and other conditions may have a similar etiology.

GENERAL SURGICAL CONSIDERATIONS

The indications and the type of operation for the removal of a single stone that is too large to pass spontaneously have been fairly well standardized. In the past, nephrolithotomy was the operation of choice for removal of a renal stone, but except for a stone or stones situated just beneath the renal capsule or impacted high in one of the calices, pelvolithotomy is now the

preferable procedure. This especially is true for the single stone that is situated in the renal pelvis. By careful manipulation, many single or multiple stones situated in the calices can also be removed through incision of the renal pelvis. Removing stones through the renal pelvis does not destroy important structures, large blood vessels are not divided and a satisfactory anatomic closure can be obtained. Urinary fistulas very rarely follow this procedure. Pelvonephrolithotomy is used to distinct advantage when a stone is impacted in a calyx, or if there are branches extending into one or more calices. By introducing the finger through the pelvic incision, the stone or stones can be pushed toward the cortex, which not infrequently is scarred or somewhat thin over this region and, by making a small incision through the cortex or by using a pointed forceps as advocated by Judd and Scholl,²⁰ the stones can quite easily be extracted. When an upper or lower calyx has been greatly dilated by the presence of large or multiple stones and accurate drainage cannot be reestablished, Herbst²¹ advised resection of that portion of the kidney. Occasionally the renal pelvis is small or mostly intrarenal. In such cases more of the pelvis can be exposed by gentle retraction of the parenchyma with a flat ribbon retractor, thereby greatly facilitating removal of stones from such pelves.

Which surgical procedure is best in the management of multiple stones cannot be dogmatically stated, since the choice of procedure must be governed largely by clinical judgment in a given case. In the past decade there has been a decided tendency toward conservative surgical measures for renal stones. It is a simple procedure to remove a kidney for stone, but it requires much experience and several technical aids to remove all stones or stony fragments and to preserve the kidney. In the presence of extensive infection with great destruction of renal tissue nephrectomy is the wisest procedure. This particularly is true if the opposite kidney is normal. Nephrectomy for single or multiple stones without infection should be condemned.

Conservative operations depend on the type, size and situation of the stones, the presence or absence of infection, status of the opposite kidney, whether or not the stones are bilateral or unilateral, on renal function, and on the general condition of the patient. An elderly patient with renal stones, for whom operation would be a great risk and who is not having many symptoms, should not be subjected to operative treatment. Cardiac lesions of the coronary type, even in middle life, must be regarded as an important contraindication to surgical removal of renal stones of the silent type. The risk of the cardiac lesion may be greater than that attending removal of stones.

Considerable controversy still exists regarding management of the stag-horn or coral-form type of stone. The reason is that they often are symptomless and are discovered only during routine examination, their removal usually has been difficult and attended with considerable destruction of renal parenchyma. Mathe²² advised that, if a patient presenting coral-shaped stone of one or both kidneys gave a history of passing fragments, operative intervention should be instituted at once. In proof of his statement he cited five cases in which fragments broke off and produced obstruction in

various portions of the ureter, necessitating emergency procedures. The late Dr Geraghty²³ advised against removal of such stones on account of the extensive injury incident to their removal and the frequency of recurrences, on the other hand, Livermore, and Kelly and Burnham,²⁴ advocated their immediate removal, correction of any stasis, elimination of infection, and frequent postoperative examination.

In the past few years we have been able to remove successfully stag-horn stones from the kidney in most cases, in several of these cases the stones were bilateral, serious injury to the kidney, its pelvis, or ureter did not take place, and all fragments were removed. The method employed in removal consisted of retraction of the parenchyma to the bifurcation of the calices, as suggested by von Lichtenberg thus giving direct access to the calices through a V incision in the renal pelvis. By nephrotomy over each calix, the portion of stone in that calix was removed, the forefinger of each hand being used, one in the pelvis and one in the calix. Bleeding from the parenchymal opening was controlled by suture or by Pezzar catheters pulled snugly up into the calix.

The surgical treatment of bilateral renal lithiasis is a problem that requires mature judgment and care. There are many who believe that, if the stones are of the aseptic or primary type, surgical removal is contraindicated, provided the stones are small, are not fixed in a calix, do not cause symptoms, and do not interfere with urinary drainage, and that all other aseptic stones which from their situation and size are likely to injure the renal parenchyma should be removed surgically. If infection is superimposed, then the stones should be removed as early as possible before extensive renal injury takes place. After the stones are removed completely, the problem is one of eliminating infection and of restoring renal function. A kidney that is obstructed and infected may appear from clinical examination to have little if any functional capacity, but at operation it may be found to possess much sound renal tissue that may be valuable to the patient, especially if the opposite kidney also is injured.

Cabot²⁵ has pointed out the value of nephrostomy for infected and obstructed kidneys in providing a method of immediate drainage, which is so essential in these cases and which promotes elimination of infection. Nephrostomy for drainage is superior to pyelostomy, by virtue of the fact that urinary fistulas rarely occur and the wound closes rapidly following removal of the tube.

The frequent reports in the literature of the occurrence of calculi in solitary kidneys serve to emphasize the importance of this urologic problem. Beer²⁶ in 1916 advocated early surgical removal of stone from the ureter in the presence of solitary kidney. Keyes²⁷ in 1930 reported five cases in which the surgical removal of such stones was successfully accomplished. The severity of the disease is shown by the report of fifty-two cases by Walters and Wright²⁸ wherein stones were removed from the remaining kidney with a

mortality rate of 14 per cent. The necessity for early removal of the stones before renal injury or infection has set in can hardly be overestimated. One of us recently removed a large triangular stone from the pelvis of a solitary kidney, this stone had completely blocked the ureteropelvic juncture about twenty-four hours previously. Following the removal of the stone by pelvolithotomy, the kidney was temporarily drained by nephrostomy for a period of ten days, when the tube was removed. Renal function returned rapidly and infection gradually subsided.

RECURRENT AND PROPHYLACTIC CARE

The mere surgical removal of stones from the kidney no longer constitutes adequate treatment for renal calculi, as the postoperative care and management forms one of the more important phases of the treatment. Particularly is this true if infection is present in the urinary tract or a definite tendency toward recurrent calculi has been demonstrated, and if renal function is materially interfered with, subsequent attention to these factors is of particular importance. The incidence of recurrence of renal stones has been variously estimated. Braasch and Foulds²⁹ in 1924 reporting 504 cases found recurrent calculi in approximately 10 per cent of them. Others have reported reformation of stone in from 30 to 40 per cent. Undoubtedly, small remnants of calculi not removed at the operation may account for certain cases of so-called recurrence. Despite this fact, however, a certain group of patients presents a definite tendency toward reformation of calculi. These individuals are similar in many respects to those patients who have recurrent ulcers following operation for peptic ulcer. In both types of cases, although the exact etiologic factors responsible for the disease remain undetermined, sufficient is known concerning apparently contributing causes to render preventive measures worth while. In brief, efforts directed toward prevention may be applied with consideration of five main points:

1 *Complete Removal of Stones*—It appears obvious that all calculi and stony fragments should be completely removed at the time of operation if recurrence is to be prevented. This may be accomplished only by the routine use of fluoroscopy and roentgenographic examination at the time of operation. With these aids, in association with careful surgical technic in order to avoid any undue trauma or bleeding, all of the stony fragments may be removed in practically every case. In rare instances it may be advisable, if a few minute fragments remain which cannot be removed without causing considerable trauma to the kidney to forego total removal of all remnants in order not to jeopardize renal function.

2 *Complete Relief of Renal Obstruction*—Although the exact part played by obstruction of the kidney in the formation of stones is not fully understood every effort should nevertheless be made to provide free drainage of urine from the upper portion of the urinary tract following removal of stones. Not infrequently, because of obstructing factors such as anomalous vessels, bands of fibrous tissue, acute angulation of the ureter or other causes, obstruction may be discovered at the ureteropelvic juncture. This should be corrected, if possible, at the time of operation. The almost certain development or persistence of infection secondary to obstruction is well known, and it accentuates the

importance of free drainage. In very exceptional cases, retrograde ureteral dilation may be indicated; however, it is exceptional in our experience to find renal calculi associated with true stricture of the ureter, and retrograde dilation seldom seems indicated.

3 Elimination of Infection—At present, complete elimination of infection is one of the most important requirements in preventing subsequent formation of calculi. Different aids may be utilized in removing infection from the urinary tract. If the kidney is found to be rather extensively injured and to be the seat of marked infection at the time of operation it frequently is advisable to insert a nephrostomy tube, preferably through the lower calyx, in order to aid rehabilitation of the kidney. This not only provides excellent drainage but permits of direct pelvic lavage as often as desired. Gratifying results frequently are noted in the restoration of renal function and in the eradication of infection by the use of nephrostomy. Occasionally, if the kidney has not been drained by nephrostomy, pelvic lavage by means of the ureteral catheter, with silver nitrate, phosphoric acid or other solutions may be helpful in sterilizing the upper portion of the urinary tract.

Before any treatment can be intelligently planned against infection of the urinary tract accurate information should be obtained regarding the exact type of offending bacteria. This necessitates cultures from the pelvis of the kidney and also from any stones that are removed. Strangely enough, the organism found in the stone may be different from that discovered in the pelvis of the kidney. The elimination of coccus forms and urea-splitting organisms from the urinary tract is essential if recurrent calculi are to be avoided.

Considerable has been written regarding various medicinal measures and the dietary treatment of infection in the urinary tract. It has been our experience that the best results are obtained by acidification of the urine with ammonium chloride or ammonium nitrate given in association with methenamine if the offending organism belongs to the bacillary group. Methenamine is most effective if a pH of the urine of at least 5.4 is obtained. If cultures reveal cocci the nonspecific use of neoparsphenamine frequently is efficacious. When measures of this type fail to produce the desired results the production of ketosis by the use of the ketogenic diet often will be effective.³⁰ A possible relationship between foci of infection and renal calculi makes³¹ desirable removal of all sources of chronic infection.

4 Correction of Metabolic Disorders—Various metabolic disorders may fundamentally be responsible for the formation of calculi. A routine chemical analysis of the calculus removed may aid in the detection of these disorders. In addition microscopic examination of the urine may reveal cystinuria or uric acid crystals.

The association of hyperparathyroidism with renal calculi has been mentioned previously, and although this condition is relatively uncommon, estimations of the amounts of calcium and phosphorus in the blood and roentgenographic study of the bones may be advisable to exclude the possibility of hyperfunction of the parathyroid bodies.

5 Periodic Examinations—Periodic examinations of the urinary tract are desirable following removal of stones from the kidney. In many cases this may seem unnecessary and may be discontinued after several such examinations. On the other hand, if the patient presents a tendency toward persistent or recurrent infection in the urinary tract, or if he has impaired renal function or faulty drainage from the kidneys, periodic examinations are desirable for a number of years. This enables one to detect in its early stages any change in the condition of the patient before injury becomes too extensive to remedy. Stones may be recognized when they are still small, and infection may be combated before function is impaired further.

ABSTRACT OF DISCUSSION

DR JEROME M. LYNCH, New York. I feel honored at being invited to discuss a topic before this assembly of specialists. At first glance there seems to be no contact between urology and diseases of the colon, rectum and anus, and yet you and I are deeply interested in the derivatives of the cloaca. Our fields are chiefly concerned with excretion. In casting about for etiologic factors in urinary lithiasis, certain indicators may point a way of investigation. Focal infection has been stressed for twenty years, and though the evidence is not convincing to me it is good practice to check possible foci and suppress or eliminate those found to harbor infection. More important is the recent work defining the influence of certain parathyroid disturbances in producing stone in the urinary tract. This, I am sure, has furnished the necessary stimulus to the urologist to keep in mind the extra-urinary possibilities in the etiology of stone. I have been interested in the gastro-intestinal symptoms displayed in many stone cases. The mimicry of appendicitis by right ureteral stone is a commonplace to urologists. Similarly attacks resembling gallstone colic or subacute obstruction occur with obstructed or infected kidney stone cases. Duodenal and gastric ulcer may be simulated by kidney stone in the absence of infection. Indeed, the periodicity associated with chronic peptic ulcer may be simulated in a striking manner. Hematemesis has occurred and no lesion except a kidney stone found. The syndrome called spastic colon can occur to disappear following removal of the stones. It is apparent that the kidneys deserve the close attention of gastroenterologists and other internists in cooperation with urologists in the solution of resistant cases of dyspepsia.

DR RICHARD CHUTE, Boston. I congratulate Drs. Counsellor and Priestley on their summary of the present-day conception of renal lithiasis. They mention the frequent occurrence of calcium phosphate stones in hyperparathyroidism. I have seen a number of cases of hyperparathyroidism and learned something about this comparatively new condition from colleagues at the Massachusetts General Hospital who have done pioneer work in calcium metabolism. Hyperparathyroidism is due to an excess of the internal secretion of the parathyroid glands, which excess comes from either a benign adenoma or hyperplasia of one or more of the four parathyroids and results in raising the blood calcium, lowering the blood phosphorus and causing a greatly increased amount of both calcium and phosphorus to be constantly excreted by the urine. The very frequent occurrence of calcium phosphate lithiasis, ranging from large calculi down to minute multiple stonelets or calcifications throughout the tubules of the kidney cortex, is consequent to the large amount of calcium and phosphorus concentrated in the urine—in one case seven times the normal amount of urinary calcium. Since this stone formation depends on a general metabolic disturbance, these calcium phosphate stones tend to be bilateral and multiple and to recur until the underlying metabolic disturbance has been remedied. One patient had recurrent bilateral calcium phosphate calculi over a period of ten years until the cause was discovered and corrected. Cases of hyperparathyroidism are not rare. The Massachusetts General Hospital has accumulated a series of nineteen proved cases of which fifteen were urinary lithiasis, which was bilateral and multiple in more than half. In the last fifteen months about 10 per cent of all stone cases that have

come to the Massachusetts General Hospital have been found to present an underlying hyperparathyroidism. The diagnosis is easily made and depends entirely on the finding of a high fasting serum calcium (the normal is 10 mg per hundred cubic centimeters, the average in the nineteen cases was 14 mg), and a low serum phosphorus (the normal is 4 mg per hundred cubic centimeters, the average in the nineteen cases was 2.6 mg). In addition to the usual urologic treatment for calculi the only adequate treatment to date for hyperparathyroidism itself is surgical removal either complete or subtotal of the adenomatous or hyperplastic gland tissue which has been well described by Churchill and Cope. Special diets, vitamins and radiation therapy directed to the neck has been tried without success. Surgical resection results in a rapid correction of the calcium phosphorus metabolism back to normal in both blood and urine. In eight cases each of which has been followed for at least six months (and one case for two and one-half years) since the operation, the calcium and phosphorus metabolism has remained normal.

DR. VIRGIL S. COUNSELLER, Rochester, Minn. The importance of what Dr. Chute has just said with regard to hyperparathyroidism should be stressed. It seems that this condition is definitely established as one of the etiologic factors in renal lithiasis and it may be a more important factor than it is now regarded to be. The work of Albright, Aub and Bauer at the Massachusetts General Hospital in this connection certainly must be considered epoch making in its character. I want to reemphasize elimination of infection from the kidneys when conservative operation has been done. A word should be said regarding the value of nephrostomy. Dr. Cabot has pointed out how rapidly an infection can be eliminated from the kidney by temporarily retaining the conditions produced by nephrostomy. This I have observed many times. Too when one traumatizes a kidney considerably in the removal of stones particularly branched stones nephrostomy is certainly a very protective mechanism and this is also more true when one is dealing with a solitary kidney.

MANAGEMENT OF URETERAL STONE

OPERATION VERSUS EXPECTANCY AND MANIPULATION

FREDERIC E. B. FOLEY, M.D.

ST. PAUL

• In recent years, ingenious devices and methods have been perfected for the passage or removal of ureteral stones without resort to operation. Properly employed they have proved of great value and have reflected much credit on urology as a specialty. Among urologists management of the condition according to this so-called conservative plan has become very popular and quite generally is regarded as the method of choice. There is much evidence that this attitude has carried too far and that the just purpose of such management is becoming subordinate to mere zeal for its use.

Conservatism in surgery deserving the name must have as its object welfare of the patient, and this must not be confused with the surgeon's zeal or prejudice for a particular method. The patient's welfare is a many-sided objective in which mortality, morbidity, suffering, duration of disability and economic factors all are concerned.

Management of ureteral stone by expectancy and manipulation is enthusiastically described in published papers, in discussions at meetings and in the casual comment of colleagues. Very often pride is displayed in having effected the passage or removal of a stone

without operation, but frequently the undesirable features of such methods are overlooked, or at least their morbidity, mortality and hardships are considerably underestimated. Only stones of very small size, ones no larger than a wheat kernel, give any promise of prompt passage or easy removal. Occasionally with these, and very frequently with stones of only slightly larger size expectancy and manipulation lead to unforeseen difficulties, risks and hardships. The severe pain of many colics may be required for the stone to progress into manipulative distance. During this period dilatation of the ureter and pelvis and extensive kidney damage may occur. After the stone has reached the pelvic ureter the turmoil of several cystoscopic procedures may be necessary for its removal. During this whole period there is the constant threat of acute infection and all that it may entail. Finally there is the chance of ultimate failure and the necessity for pelvic ureterotomy, a distinctly major and at times difficult operation. Such a sequence of events is indeed deplorable in cases in which the stone was first discovered in the lumbar ureter before any notable damage had occurred, before the patient had had any great hardship and in which there was or should have been opportunity for immediate and easy removal by simple and relatively minor lumbar ureterotomy.

If proper conception of what really constitutes the patient's welfare is borne in mind and mere prejudice in favor of the word conservatism is laid aside, careful consideration makes it very apparent that much of the so-called conservative management of ureteral stone is radically conservative is without intelligent purpose and should be abandoned in favor of open operation. This assertion does not belittle the great value of these procedures when properly employed or detract from the credit due their originators. Merely it points out that their great worth can obtain only when the patient's welfare is their object and is not subordinated to zeal for their employment.

In the management of ureteral stone, either expectancy and manipulation or open operation must be determined on. In making this decision no general comparison between the two methods is applicable, for numerous factors such as the size of the stone and the presence or absence of infection have a bearing and are extremely variable among different cases. Considerations regarding the decision usually give no great importance to position of the stone and make no particular distinction between the magnitudes of lumbar ureterotomy and pelvic ureterotomy. Pelvic ureterotomy is always an operation of distinctly major character. Lumbar ureterotomy, as described in textbooks and as usually seen is also a definitely major operation, it can and should be a relatively minor one. A method and technique for lumbar ureterotomy have been perfected and are described here that so minimize the operation that in this form it scarcely belongs to major surgery. Accordingly in the present consideration of the two methods of management, and particularly in comparisons of expectancy and manipulation with open operation, pelvic ureterotomy is sharply distinguished from lumbar ureterotomy by this particular method, and position of the stone, whether it affords or does not afford opportunity for this procedure, becomes an important factor in determining between the two methods of management. Decision between the two methods thus should differ greatly depending on whether lumbar or pelvic ureterotomy is involved.

Lumbar ureterotomy, even by former methods, should always be of more minor character than pelvic ureterotomy, but proper recognition and appraisal of this important point in the management of ureteral stone has not been properly emphasized and has not been practiced. In the urologic service of the Ancker Hospital and in private practice the method I have per-

Fig 1—Lumbar ureterotomy. Incision. Patient in "kidney position." The kidney elevator of the operating table is raised only enough to widen the space between the twelfth rib and the ilium but not enough to put the muscles under tension. The incision from 10 to 12 cm long exposes the posterior edges of the external and internal oblique muscles and the anterior edge of the latissimus dorsi muscle. The lumbodorsal fascia presents between the muscles or is exposed by slightly separating them.

fected for lumbar ureterotomy has greatly emphasized for my associates and me the importance of this consideration, and we have come to the conclusion that, in the management of ureteral stone, opportunity for this procedure never should be neglected in favor of expectancy and manipulation, except in cases of stones so small that prompt passage or easy removal is almost certain. Accordingly, when a ureteral stone larger than a wheat kernel occupies a position above the pelvic brim it is removed at once by open operation, even though its small size meets the former criterion favoring management by expectancy and manipulation. Only stones of truly minute size are allowed to progress into the pelvic ureter for spontaneous passage or manipulative removal.

If the stone is already located in the pelvic portion of the ureter the considerations are quite different, for pelvic ureterotomy is a much more major procedure and expectancy and manipulation should be employed unless the stone is of such large size as to give little prospect for the success of such management.

The technic of lumbar ureterotomy as described in textbooks and as usually observed in practice does not properly take advantage of anatomy toward the ends of simplicity, accuracy and minimal trauma. General anesthesia is employed, an unnecessarily large incision is made, muscles are divided, and the ureter is identified and exposed by unwarrantedly extensive and inaccurate dissection of retroperitoneal structures. Such a procedure is time consuming and accompanied by shock and risk in a superfluous degree. All this can

be avoided in favor of local anesthesia, a small incision without division of muscle fibers, accurate identification and exposure of only the stone containing segment of ureter, and with almost no disturbance of retroperitoneal structures. When the operation is so performed it may be done in a brief time, with accurate closure of the ureter by suture and without drainage of urine from the wound. Such an operation imposes less risk and usually less discomfort than removal of the stone by expectancy and manipulation. The convalescence is rapid and there is a minimal period of disability.

The operation so performed takes properly into account the position of the ureter close to the vertebral bodies, its course through the fat containing space between the two layers of pararenal fascia (of Gerota) and the clean cleavage plane between the posterior layer of this fascia and the muscles of the abdominal wall—the quadratus lumborum and iliopsoas. The dissection is anatomically accurate and almost entirely by blunt opening of cleavage planes between structures.

TECHNIC OF OPERATION

Local infiltration anesthesia using 1 per cent procaine hydrochloride containing 10 drops of epinephrine per ounce (30 cc) is made in the line of incision. The infiltration is extended deeply into the muscles on each side of the incision and into the retroperitoneal space of the flank. With the patient securely fixed in the

Fig 2—Lumbar ureterotomy. Freeing of muscles. Exposure of lumbodorsal fascia. The undersurface of the internal oblique muscle is bluntly separated from the lumbodorsal fascia. This permits the internal oblique and external oblique muscles to be drawn well forward. The latissimus dorsi, already bluntly separated from the fascia is drawn backward. A wide area of lumbodorsal fascia is exposed.

"kidney position," the elevator is raised only enough to widen the space between the rib and the ilium without putting the flank muscles under tension.

The incision, from 10 to 12 cm in length, is placed on a line extending in vertical oblique direction from the middle of the twelfth rib toward the anterior supe-

rior spine of the ilium (fig 1) The level of the incision on this line is made appropriate to the level of the stone Division of the skin and subcutaneous fat exposes the posterior edges of the external and internal oblique muscles and the anterior edge of the latissimus dorsi muscle midway between the twelfth rib and the iliac crest These muscles are made freely mobile by bluntly separating their undersurfaces from the lumbodorsal fascia on which they lie (fig 2) This permits the oblique muscles to be drawn well forward and the latissimus dorsi well backward, with exposure of a wide area of lumbodorsal fascia The lumbodorsal fascia is now split parallel to its fibers with exposure of the posterior layer of the pararenal fascia (fig 3) Except for a thin layer of intervening fat (pararenal), this fascia lies directly in contact with the muscles of the posterior abdominal wall, the quadratus lumborum and the iliopsoas It passes posterior to the ureter and kidney and onto the vertebral bodies medial to them (fig 4) This fascia and the anterior layer of pararenal fascia form an envelope completely enclosing the perirenal and the periureteral fat Instead of immediately opening this fascia to approach the ureter through its surrounding fat, as is usually done, the dissection takes advantage of the clean cleavage plane between the posterior layer of pararenal fascia and the muscles on which it lies By blunt dissection this cleavage plane is opened by gently stripping the fascia away from the muscles behind it The stripping is continued medially to the vertebral bodies, even disclosing the position of

lateral to the vertebral bodies and immediately under the fascia, for most of the periureteral fat lies anterior to the ureter (fig 5) The position of the stone is marked by a bulge in the course of the ureter, or if not evident in this way it may be felt by passing a finger along the course of the ureter With a curved or somewhat hooked point scalpel a longitudinal incision is made through the fascia and ureter over the stone,

Fig 4—Lumbar ureterotomy Horizontal cross section at level of proposed ureterotomy (intraperitoneal structures not shown) Note the relations of the pararenal fascia (fascia of Gerota) to surrounding structures and to the ureter and fat that it surrounds Apart from incision of the skin and the subcutaneous fat and blunt splitting of the lumbodorsal fascia parallel to its fibers the exposure thus far is accomplished entirely by blunt opening of cleavage planes between structures Opening the pararenal fascia and the usual method of approaching the ureter by dissection through the fat are carefully avoided

Fig 3—Lumbar ureterotomy Separation of pararenal fascia from muscles of the posterior abdominal wall The lumbodorsal fascia has been split parallel to its fibers exposing the posterior leaf of pararenal fascia The pararenal fascia completely invests the periureteral and perirenal fat It lies in contact with peritoneum in front and muscles of the abdominal wall behind The clean cleavage plane between the pararenal fascia and the muscles of the posterior abdominal wall is being opened by blunt dissection

the aorta or cava, and in an upward or downward direction, as determined by the position of the stone With the pararenal fascia and the contained fat elevated and held forward away from the muscles by a Deaver retractor, the ureter will be seen as a pale ribbon-like streak running longitudinally 3 or 4 cm

with removal of the latter The ureter is not further explored and bougies or olives are not passed into it The opening in the ureter is securely closed by a continuous suture of 0000 catgut affixed to a fine atraumatic needle The suture includes only the muscularis, with careful avoidance of the mucosa The wound is closed without drainage (fig 6) The lumbodorsal fascia is closed with a continuous suture, but the muscles fall into place and do not require approximation

COMMENT

The operation as described can be performed in from fifteen to twenty minutes and with practically no shock Thus far there has been no fatality, and the risk to life has appeared negligible The postoperative courses have been entirely without incident, the patients have been out of bed on the second or third day and ready to leave the hospital on the fifth to the seventh day By comparison with expectancy and manipulation, the risk, damage to the kidney, hardship for the patient, period of disability and uncertainty of outcome have been vastly less

Usually a stone in the lumbar ureter produces typical symptoms and physical changes When these are accompanied by a shadow in position of the ureter, the shadow usually can be localized and positively identified as a ureter stone by excretion urography, even in patients of very large stature If changes demanding

further investigation are not thus disclosed, the hardship of cystoscopy and ureteral catheterization may be entirely avoided

A stone in the lumbar ureter giving a radiographic shadow of 5 mm or more in the greatest dimension should be removed at once by lumbar ureterotomy. When such a stone has already reached the pelvic ureter, expectancy and manipulation by all means should be tried. The hardship of the several colics required to advance it to this position, the damage to the upper urinary tract that has already occurred and the discomfort of the manipulative procedures to be employed cannot be undone. Such a stone and even ones of larger size may appear susceptible of easy removal. Attempts to remove it may not verify this. If the stone remains in this position sufficiently long extensive changes requiring nephro-ureterectomy may occur, even in the absence of painful symptoms. It is a fool's enterprise to persist in manipulative procedures, frequent colics continuing damage to the kidney and the grave risk of acute infection. Even pelvic ureterotomy is to be preferred to such a course and should be resorted to when one or at most two attempts at manipulation have failed.

In cases of ureteral stone in which there is or should have been opportunity for lumbar ureterotomy as described here, expectancy and manipulation should be considered only in cases of stones so small that there is almost positive assurance of passage or removal with-

pose, is radically conservative and should be abandoned in favor of the truly conservative procedure described here

SUMMARY

1 Management of ureteral stone by expectancy and manipulation has been employed too extensively. Their morbidity, mortality and hardships are underestimated and their just purpose is often subordinated to mere

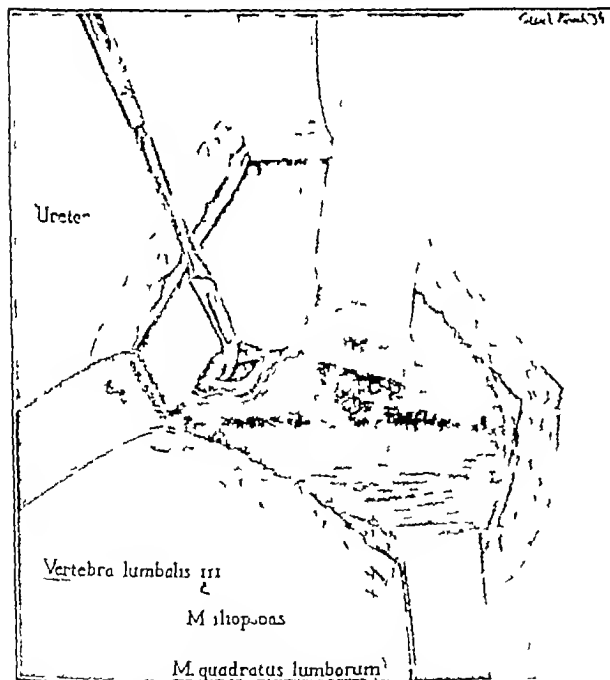

Fig 5—Lumbar ureterotomy. Exposure of ureter and removal of stone. The pararenal fascia has been stripped up from the muscles of the posterior abdominal wall mediat to the vertebral bodies. The ureter covered only by the thin fascia is readily identified as a pale ribbon-like streak. A stone within the ureter is marked by a bulge or may be identified by passing a finger along its course. The pararenal fascia overlying the ureter has been split and the ureter is being incised over the stone. The opening in the ureter will be closed with a continuous suture of 0000 catgut in the muscularis with care not to include the mucosa.

out difficulty. To accept the risks, hardships and uncertainties of expectancy and manipulation in any but such cases of lumbar ureter stone is bad judgment and betrays blind prejudice in favor of expectancy and manipulation. Such conservatism lacks intelligent pur-

Fig 6—Lumbar ureterotomy. Closure of wound. The "kidney elevator" of the operating table has been lowered permitting the wound edges to approximate themselves. A continuous suture of number 1 chromic catgut is used to close the lumbodorsal fascia. The muscles fall into place and need not be sutured. In most cases even a superficial drain is not left in the wound.

zeal for their use. Such methods are truly conservative only when they best serve the patient's welfare.

2 Lumbar ureterotomy should always be of more minor character than pelvic ureterotomy. This fact is not properly recognized. It always should be taken into account in determining between "expectancy and manipulation" and "open operation."

3 Lumbar ureterotomy, as usually described and observed, is a distinctly major operation and does not properly take advantage of anatomy toward the ends of simplicity, accuracy and minimal trauma.

4 The improved method for lumbar ureterotomy that has been described takes advantage of anatomy toward the ends of simplicity, accuracy and minimal trauma and greatly minimizes the procedure.

5 A lumbar ureter stone of greatest dimension 5 mm or more should be removed at once by lumbar ureterotomy, as described here. Only stones of truly minute size should be allowed to pass into the pelvic ureter for spontaneous passage or manipulative removal.

229 Lowry Building

ABSTRACT OF DISCUSSION

DR. WILLIAM J. ENGEL, Cleveland. I am in almost complete agreement with Dr. Foley on manipulation of stones in the ureter. The multiplicity of methods advocated for manipulative removal of stones in the ureter is proof of the inadequacy of any one procedure. I have employed multiple catheters, the spiral stone extractor and dilation of the ureter below the stone with bougies and have been impressed with the infrequency with which the stones have been satisfactorily removed by these

means In my experience manipulative procedures often give rise to sharp reactions associated with chills, fever and rather marked prostration Manipulation may well traumatize the ureter and ureteral mucosa sufficiently to produce stricture Additional disadvantages are the prolonged period of time that is usually necessary to secure the passage of the stone, during which time the patient is in constant fear of recurrent colic and the period of morbidity is distinctly increased by the manipulative procedures Too often final resort to open operation is necessary after the patient has been exhausted by the preliminary procedures I have favored open operation for the removal of stones in the ureter in the vast majority of instances The situation of the stone is important in making the decision Contrary to Dr Foley's experience I have found most stones in the lower or pelvic portion of the ureter In a series of 268 cases reviewed recently, the stones were in the pelvic portion in 205 instances I must disagree with the author that removal of a stone from the pelvic portion of the ureter is an operation of great magnitude The operation described by Dr Lower consists of a muscle-splitting incision carried out entirely extraperitoneally and is not difficult Its success depends on extremely careful dissection of the ureter and the avoidance of bleeding The external and internal oblique muscles are divided much as in a McBurney incision and the peritoneum is retracted medially until the ureter is found Then by picking it up with Allis forceps and dissecting it down, one can follow the ureter all the way down to the bladder When the stone has been located it is fixed between two clamps and then a small longitudinal incision is made over it and the incision is closed with drainage I have not had the courage to close these wounds without drainage as Dr Foley has In the series of operations for pelvic ureteral stone the average postoperative stay in the hospital was ten days although many patients have been dismissed on the fifth, sixth and seventh day In an occasional case in a woman when the stone is stuck in the lower pelvic ureter and can actually be palpated on vaginal examination the cervix is drawn to one side a little longitudinal incision is made and the stone is palpated and removed These patients are out of the hospital sometimes within four or five days

DR F C HERRICK, Cleveland I do not agree with the author that ureteral calculi should always be operated on as soon as diagnosed Dr Crowell of Charlotte, N C recorded his method of removal of these stones by the passage, first of a small ureteral bougie, followed up by another perhaps two or three or four bougies, followed possibly by a small catheter or a larger catheter so that he can get at times three bougies or catheters by such a stone This is followed by injection of a small amount of oil and a wait of twenty-four hours when these stones slide as it were down the bougies I think that 75 or 80 per cent can be gotten that way I think that one is too hasty in taking the step of immediate surgical removal I remember a case first diagnosed by Dr Braasch of Rochester Minn A stone was carried around for some twelve or fifteen years I got it at the lower end of the ureter It was huge, larger than one would expect to pass by this method The patient was so much relieved that he left the hospital at once and would not let me get it out of the bladder Dr Lower took it out of the posterior urethra by incision It came down nevertheless by this bougie method Twenty-five years ago I described in Binney's Surgery an operative technic for access to the lower ureter It was an intermuscular incision from an inch above the anterosuperior spine in a line with the opposite spine of the pubis It allows one to split both oblique muscles and affords easy access to the ureter Although I devised that method and used it a number of times I have rarely taken out a ureteral stone by incision since the idea of the catheters and the bougies up the ureter came along I have gotten almost all of them the other way It does not seem reasonable or safe to make an abdominal incision open the ureter in the presence of frequently infected urine, close the ureter and the abdomen without a drain and send the patient home in five or six days as has been suggested by Dr Engel The danger of leak and infection is such that although a primary closure may result in primary union, a small cigaret drain to the site of the ureteral opening appears advisable

DR. FREDERIC E B FOLEY, St Paul In spite of the facility with which Dr Herrick and Dr Engel perform pelvic ureter-

otomy, I am convinced that the operation for removal of a stone from the ureter down close to the bladder is technically a much more formidable procedure than lumbar ureterotomy of the sort I have described The reason so many more stones are seen in the pelvic ureter than in the lumbar ureter is not the fault of the urologist but the fault of the general practitioner who sends the patient to us When pain suggestive of renal or ureteral colic occurs, a urinary tract x ray film should be made at once I make a plea with the general practitioners to recognize these lumbar ureter stones promptly and to have them removed in the safe quick and easy way I have described rather than to accept the hazards and uncertainties of expectancy and manipulation

AN INVESTIGATION OF THE NEW BIOLOGIC TEST FOR HORMONES IN PREGNANCY URINE

PRELIMINARY REPORT

ISRAEL S KLEINER, PH D

ABNER I WEISMAN, MD

AND

HARRY BAROWSKY, MD

NEW YORK

Kanter, Bauer and Klawans,¹ basing their work on previous experiments of Tozawa,² Fleischmann and Kann³ and Szusz⁴ have recently reported experiments on a new biologic test for hormones in pregnancy urine in which they intimate the usefulness of the female bitterling in the diagnosis of pregnancy They used the lengthening of the female ovipositor as a criterion of positive reaction for the hormones of pregnancy urine and suggested a method of standardizing the female bitterling, believing that "it was necessary to know in advance whether each fish was capable of responding positively to urine from a known pregnant woman and that the same fish would not react to the urine from a patient who was not pregnant"

In their technic a standardized fish (presumably a Japanese bitterling) was placed in a 2 liter bowl half filled with water to which 4 cc of the urine to be tested was added After seventy-two hours, final readings were taken A lengthening of the ovipositor from a normal of from 2 to 5 mm to from 15 to 25 mm was considered a positive reaction Thirty-one cases of doubtful pregnancy were reported, with twenty-seven absolutely checked by the Friedman test and with four discrepancies between the two tests These results seemed so promising in the face of the fact that Szusz reported such unfavorable results, using a wider range of controls, that we decided to repeat their work

We were fortunate enough to obtain a supply of female bitterlings (*Rhodeus amarus*) from the New York Aquarium This fish resembles the Japanese bitterling very closely in size and appearance and has the same sexual apparatus and the same breeding habits Each fish was examined and was said to be mature and

in good health⁸ with the ovipositor presenting externally in the quiescent state from 2 to 5 mm in length. The first thing which came to our attention was that, after we had transported the fish and placed them in our stock tanks two out of fifty showed elongated ovipositors from merely being handled. These ovipositors were at least 25 mm in length and regressed overnight after being placed in our large tank.

The question of the necessity of "standardization" was first considered. According to Kanter, Bauer and Klawans the fish should be standardized before use. They maintain that the test fish must show a positive elongation produced by a known pregnancy urine and that the same fish should not react to a urine from a patient who is not pregnant. In our opinion standardization is neither feasible nor scientific and our results bear out this statement.

TECHNIC

A mature fish was placed in a 2 liter bowl containing 1,500 cc of water. Six cc of the urine to be tested was added to each bowl. The fish were observed at twenty-four hour intervals for seventy-two hours. Elongation of the ovipositor to at least 25 mm was taken as a positive reaction, a length of 15 mm was considered a moderate enlargement (doubtful), about 10 mm was called slight enlargement, (probably negative), and a negative reading was an ovipositor measuring 5 mm or less. Forty-six fish were placed in individual aquariums. Five groups of urine were tested. After forty-eight hours most of the fish had either reacted positively or not at all and the seventy-two hour reading showed little or no variation from the forty-eight hour reading.

RESULTS

Group 1 Twenty-one female bitterlings were tested with known pregnancy urines. Of these, eight tests were negative, nine were definitely positive and four showed some enlargement of the ovipositor.

Group 2 Urines from seven normally menstruating nonpregnant women were tested by the fish method with the result that four gave positive ovipositor tests.

Group 3 Samples of urine from four different normal males were tested, with one positive result. This positive result was so striking and occurred so rapidly (before forty-eight hours) that we obtained another specimen from the same individual, a healthy normal man, aged 21. This was tested on six fish in separate aquariums with positive results in every fish within forty-eight hours.

Group 4 Three samples were obtained from women who were in the postclimacteric period and had not menstruated for from four to seven years. Each urine of this group was tested on two fish. One urine gave a positive fish test.

Group 5 The urines of group 1 (from known pregnancies) were boiled and tested in the same way. In some cases two boiled urines were mixed and tested. The results were quite irregular, some boiled urines giving positive reactions and some negative.

COMMENT

It will be seen that only nine of the twenty-one urines from pregnant women gave definitely positive reactions. Of seven from normally menstruating nonpregnant women, four gave positive reactions. One male urine

of the four tested was positive, and a later specimen from the same male gave positive reactions in every one of the six fish tested. Urines from women who had passed the menopause were positive in one of three cases. Boiled urines from pregnant women were positive in some instances and negative in others.

These results agree with those of Szusz and indicate that this biologic reaction is not a specific test for pregnancy as Kanter, Bauer and Klawans intimate. Moreover, the latter authors do not report as great a variety of controls as we have and as Szusz previously reported. Our finding that nonpregnant female urines, postmenopausal urines, male urines, boiled pregnancy urines, and physical disturbance may bring about lengthening of the ovipositor would seem to show that a standardization of a fish, as these authors suggest, would be extremely difficult if not impossible. Whether the phenomenon is due to the presence of estrogenic substance or to some other hormone or to some other substance remains to be determined. We are continuing the investigation.

POISONING DUE TO THALLIUM SULPHATE

EDWIN P. JORDAN, MD

CHICAGO

Poisoning with thallium is still a rarity as contrasted with that of lead and mercury, owing in all probability to the relatively infrequent use of the former for industrial purposes. The toxicity of thallium is however well recognized and cases of poisoning have been described in both the domestic and the foreign literature.¹ Because of the infrequency, the strange symptomatology, the fact that treatment is not well standardized, and the probability that more widespread commercial use of thallium compounds is foreshadowed, the case reported here is of exceptional interest.

REPORT OF CASE

The patient was a man, aged 38. I was called to his home, June 24, 1934. The following history was obtained. The patient's previous health had been good; the only previous complaint being of relatively easy gastro-intestinal upsets and moderately frequent sore throats. About June 10 the patient had a slight sore throat lasting a few days. June 14 the patient, who is connected with the motion picture industry, went to a laboratory in which experiments were being performed on the development of films. While there he had a lunch consisting of a sandwich and coffee sent up from a nearby restaurant. The sandwich was unwrapped and placed on the table between bites. He noticed a crunching in his mouth and after the sandwich was eaten a metallic taste. He asked the laboratory worker what substance was being used, and was told thallium (later determined as chemically pure thallium sulphate). He was somewhat worried for a few days but nothing occurred to remind him of metallic poisoning.

For the sake of clarity the course is presented in chronological order according to the number of days following the ingestion of the thallium.

2 (noted only in retrospect) The stools were soft to semiliquid but there was only one a day. This condition persisted for four days.

3 There was moderate loss of appetite. The patient's wife noticed that his face was "flaming."

7 and 8 He began to notice a sensation of "going to sleep" in the toes. There was slight pain under the manubrium of

⁸ Mr. W. Christopher Coates, curator of tropical fish of the New York Aquarium, obtained and selected the fish for us and gave us valuable information regarding the care of the fish in our laboratory.

the sternum. In retrospect the patient believed he had some fever at this time.

8 The patient went to bed because of pain in his legs. There was a brief return of the metallic taste in the mouth.

10 This was the day of my first visit. The patient was complaining of pain and soreness at the tips of all the toes, in the proximal joints of the toes, especially the big toes, and in the knees anteriorly below the patella.

The physical abnormalities were relatively few. The blood pressure was 120 systolic 86 diastolic. The temperature was 99.4 F. The pulse was 80. All the toes were sensitive to the tips and painful to pressure and to passive motion of the proximal joints. The metatarsophalangeal joints of both feet were sensitive to pressure and felt hot and slightly swollen. There was moderate tenderness to pressure over the subpatellar region. The knee motions were free and caused only slight pain. Muscular strength of the leg muscles was good. The knee and ankle tendon reflexes were normal. There were no abnormalities noted in the lungs, heart or abdomen. The face was flushed. There was slight mental confusion. The tongue was moderately coated. The teeth and gums were normal except for several crowns. The throat was moderately reddened and there were large tonsils present. The pupils reacted to light and in accommodation. The patient appeared in general more prostrated than was accounted for by the physical changes found. My impression was one of rheumatic fever (atypical) or infectious arthritis. The patient was given sodium salicylate with sodium bicarbonate of each 4 Gm daily as an attempted therapeutic test.

11 Subjectively the feet were slightly less painful. The temperature was 99.6 F. The first complaint of marked sleeplessness was reported. The patient was still confused and prostrated. The urine was normal. The sedimentation index was 10 (Cutler method).

12 The feet were about the same. The patient complained of sharp pains in the epigastric region. He vomited several times. There was tenderness over the epigastrium. Sleeplessness was severe. He felt listless but was unable to sleep. His vision was blurred for about twenty-four hours. The pulse was 104. Salicylates were stopped. Attempted administration of bismuth subcarbonate was without effect on the nausea or gastric pain. Attempted induction of sleep on usual hypnotics was without effect. Morphine sulphate, one sixth grain (0.01 Gm) was given hypodermically.

13 The temperature was 100.2 F. the pulse 100. The white count was 14,200 with 77 per cent polymorphonuclears, 21 per cent lymphocytes and 2 per cent monocytes. The hemoglobin was 100 per cent (Dare). The patient was unable to retain food or fluids. There was marked nervousness and sleeplessness. The posterior palate showed some diffuse redness and punctiform purple red spots. There was no complaint of sore throat. An enema was followed by a retention enema at night.

14 The pulse was 104, the temperature 99.4 F. The symptoms remained the same except for some decrease of pains in the feet and knees. The patient was given no food but retention enemas every four hours.

15 Pains in the epigastrium were decreasing. The patient was able to take fluids freely with only slight discomfort. Mental confusion was somewhat lessened. Small amounts of bland foods were retained.

16 The temperature was staying between 99.2 and 99.8 F. The pulse was 104. The white count was 12,000.

17 The head hair began to fall out freely. The patient was slightly jaundiced. He still complained of sleeplessness and some gastric distress, especially after taking food. There was slight desquamation of the hands.

18 The pulse was 84, the temperature 99.4 F. There was no albumin in the urine. There had been no vomiting for five days. The joints were less painful. The patient was still listless and complaining of sleeplessness. Gastric pains were severe in the evening and at night. Sodium thiosulphate, 0.5 Gm intravenously, was administered. The hair was still falling rapidly.

19 The pulse was 100. The patient noticed a "boiling sensation" in the stomach after eating. A twenty-four hour urine specimen was collected and identification of thallium was attempted by Miss Isaacs. In spite of the cooperation of the

physics department of the University of Chicago (Professor Gale), none was ever found. Sodium thiosulphate 0.5 Gm. was administered. Light drops of dilute hydrochloric acid was given with meals.

20 The patient vomited for the first time in a week. No gross blood was seen. The vomitus was examined for hydrochloric acid. There were 28 points of free acid present. Gastric pains were much worse. Dr. L. C. Gatewood saw the patient in consultation. From this time on the temperature varied between 98.6 and 99.6 F. but gradually returned to normal. The pulse was 104. The hair was still falling out and had become scanty. The jaundice was practically gone. The chief complaints were severe gastric pains and sleeplessness. No food or fluid was taken on this day. Sodium thiosulphate 0.5 Gm. was given.

21 The pulse was 120. The white count was 18,300. Jaundice was decreasing. No food was taken. There was no vomiting but gastric pain was still severe. The patient was restless and still unable to sleep. He stated that the desire to urinate preceded the starting of the stream by about an hour. There was some pain at the beginning of the stream but none later. The stream was normal however, when started. Sodium thiosulphate 0.5 Gm. was given.

22 The pulse was 104. Fluids were taken freely. The patient vomited once. Gastric pain was present but slightly less severe than formerly. The hair was still falling out. The beard grew slowly the past week. Pilocarpine hydrochloride 1 per cent, five drops four times a day was given. The tongue was slightly coated. The gums were normal. All-day suckers were given. No sodium thiosulphate was administered.

23 The pulse was 108. The usual afternoon nausea and vomiting occurred. The jaundice disappeared. Potassium iodide was given by mouth.

24 The pulse was 116. The patient was nervous and restless, and he complained of sleeplessness. He had been able to retain little by mouth. He was still moderately confused.

25 The pulse was 108, the blood pressure 156 systolic, 104 diastolic. Pilocarpine hydrochloride five drops four times a day was given.

26 The pulse was 128. Gastric pains occurred at intervals. The patient was unable to retain food. Iodides were stopped.

27 For the following week the pulse varied between 100 and 108. The blood pressure was 152 systolic 118 diastolic. The patient's memory was better. The tongue was still coated. The abdomen was relaxed. There was moderate tenderness over the epigastrium. Gastric pains were still severe at night.

28 The blood pressure was 136 systolic 104 diastolic. The hemoglobin was 118. The urine contained a trace of albumin (acetic acid). The white count was 11,800 with 64 per cent polymorphonuclears, 33 per cent lymphocytes, 2 per cent eosinophils and 1 per cent monocytes. There was no bluish discoloration of the gums. Moderate tingling of toes and tenderness was still present.

29 The tongue was almost clear. The patient was taking food and fluids well. He was still unable to sleep.

30 The patient's memory was practically normal. He had not vomited for three days. Gastric pains were much less severe and less constant.

31 The patient felt tired and weak but was eating well.

32 The patient noticed more frequent but slightly painful micturition while taking pilocarpine. The hair was apparently not falling out any more. A few strands were left. The beard was growing more rapidly (?). Sleeplessness was the pre-dominant symptom.

33 The patient felt weak and tired.

34 The pulse was 96, the blood pressure 120 systolic, 88 diastolic. The hemoglobin was 100, the white count 8,000, the urine normal. Sodium thiosulphate 0.5 Gm. was given intravenously.

36 The pulse was 104. There was slightly increased pain in the toes.

37 The pulse was 108. The hair was beginning to grow on the head (?). Urination was still slow in starting and slightly painful before the stream began to flow.

42 The pulse was 100, the blood pressure 138 systolic, 100 diastolic. The white count was 10,000. Pain was still present at the ends of the toes.

43 The pulse was 96 The patient's general condition was improving He had been taking potassium iodide for about twenty-four hours

45 The pulse was 106 the blood pressure 134 systolic 106 diastolic There were severe cramps in the muscles of the thighs and calves

51 The white count was 9,800 the urine normal The condition remained about the same There were no important developments in the subsequent course The convalescence was gradually extended The hair grew back normally The last remaining obvious symptom was tenderness and numbness of the toes It was about three and one-half months after ingestion of the thallium before the patient was able to resume his work The blood pressure when the patient was last seen October 19, was 108 systolic, 74 diastolic The pulse was 84 The urine was normal

SUMMARY

In a case of human thallium intoxication the origin was almost certainly that amount of chemically pure thallium sulphate accidentally picked up by a sandwich placed on a table on which experiments had been performed with this substance So far as can be determined this is the first case of industrial thallium poisoning reported from the motion picture industry

The symptoms of the poisoning began gradually The most important in order of appearance were neuritic pains in the toes and feet mental excitement and confusion, sleeplessness epigastric pains and vomiting, and falling out of the hair of the head These were associated with other signs of profound physiologic disturbance, e g, fever, rapid pulse and increased blood pressure

Treatment, after correct diagnosis had been made, was symptomatic with the addition at various times of sodium thiosulphate, iodides, hydrochloric acid and pilocarpine, all of which have been recommended The alarming exacerbation of symptoms following the administration of sodium thiosulphate and iodides in the earlier phase of the illness was most striking and deserves special emphasis In this case hydrochloric acid appeared not to be indicated, as free acid was present in the vomitus

COMMENT

There are two main problems relating to thallium poisoning, both amply demonstrated in the case reported The first involves the early diagnosis and the second the treatment The rarity of thallium poisoning makes one hesitate to diagnose this condition in the face of early symptoms simulating other much more common diseases Thus, in the present case the initial impression was rheumatic fever (apparently a common mistake)² in spite of the volunteered history of alleged thallium ingestion on a sandwich Furthermore, a description of swelling of the metatarsophalangeal joints was not obtained in the first articles consulted but was later found mentioned in the article by Goodman³ The most striking and absolute clinical diagnostic feature is falling out of the head hair, but this does not usually occur until sometime during the third week following the ingestion of the poison In the reported instance, falling of the hair began on the seventeenth day There was hence, and apparently often is, a prolonged period between the occurrence of poisoning and correct diagnosis More widespread knowledge of the high toxicity of this substance should serve to reduce this delay in a majority of the cases

² Hamilton Alice Industrial Toxicology Harper's Medical Monographs New York Harper & Brothers 1934
³ Goodman Herman Thallium Acetate Its Toxicity and Depilatory Action New York State J Med 32:1307-1313 (Nov. 15) 1932

Treatment based on animal experiments has been outlined by Munch⁴ This consists in (1) intravenous administration of sodium iodide until thallium has practically disappeared from the twenty-four hour urine, (2) sodium thiosulphate intravenously to induce gradual elimination of thallium, (3) pilocarpine and calcium salts intravenously, and (4) hydrochloric acid orally Leschke⁵ says "The best agent for the treatment of thallium poisoning is sodium thiosulphate given slowly by intravenous injection in a daily dose of 20 cc of a 3 per cent solution in distilled water In addition, the water excretion should be stimulated by means of frequent drinks of tea and through purging In acute cases the stomach should be thoroughly washed out, and large amounts of milk given" These two citations serve as examples of the wide discrepancy in recommended treatment

It is obviously impossible to formulate any rational method of therapeutics from the observation of one case Certain aspects that may be of importance are nevertheless suggestive There was a marked exacerbation of symptoms following administration of sodium thiosulphate and later following sodium iodide taken orally Both of these may have been fortuitous, but both occurred at times when the patient had become almost symptom free It seems probable, therefore, that these substances have a demobilizing action on thallium, tending to bring it out of the bones or other depots into the circulation, as is the supposed action in lead and certain other metallic poisons If this hypothesis is correct, the time element and acuteness or chronicity of the intoxication become of paramount importance With the atomic weight of thallium at 204, lying between that of mercury and of lead, its behavior might be expected to be at least somewhat similar A more rational treatment, subject to real investigative procedures, in the acute and subacute forms at least, would seem to be the administration of calcium and alkalis as in lead poisoning, with the object of removing thallium from the circulation It is necessary to note however, that Lehman and Gaffney⁶ did administer calcium chloride to one patient but after five injections the symptoms became worse and this treatment was discontinued Later sodium thiosulphate and iodides might be given cautiously to attempt the reversal of this process with gradual elimination of the metal Admittedly this is speculative but seems at least as rational as the administration of five drugs simultaneously each with an uncertain mode of action

Finally, it should be reemphasized that the extension of industrial use of thallium, in this case in the developing of motion picture films, constitutes an important potential danger and may make intoxications of this nature much more frequent

NOTE—The patient was seen in my office, Jan 27 1935 At this time his only complaints were moderate listlessness and inability to walk fast because of stiffness in his feet There was no pain March 1 he committed suicide by shooting himself in the head Judging from the arrangements made for this event, there was no evidence of mental confusion remaining from the illness described in the report Although several cases of acute thallotoxicosis have resulted from attempted suicide, in this instance there were no known motives for suicide at the time of the poisoning

EMERAUDE PERFUME DERMATITIS

NORMAN TOBIAS M.D. ST. LOUIS

Instructor in Dermatology St. Louis University School of Medicine

Perfume dermatitis is not common in this country when one considers that thousands of bottles of various types and grades of perfume are sold annually. It is possible that many cases are overlooked by the physician, others may be mild in character and detected by the patient herself. Unfortunately, the literature contains very few reports of true perfume dermatitis.¹ These cases are fairly common in France.

There are three types of dermatitis that may be caused by perfume. Dermatitis venenata can be produced by irritants in the perfume coming in contact with the skin at the first application without the intervention of hypersensitivity. This type simulates benzene or turpentine dermatitis (examples of universal cutaneous irritants) and is similar to a chemical burn. At first local, it may spread and become generalized, as a result of autosensitization, a phenomenon first described by Whitfield.² Other cases are due to hypersensitization to certain ingredients such as aldehydes,orris root or dyes after prolonged contact (contact or eczematous dermatitis). A third type of perfume dermatitis first described by Freund³ in 1916 is called berloque dermatitis, a streaked erythematous eruption followed by pigmentation and produced by the action of sunlight on oil of bergamot, a common ingredient of toilet waters and cologne.

Schwartz^{3a} reports five cases of perfume dermatitis among twelve girls whose occupation consisted of bottling perfume. In one of the cases the eruption was severe enough to cause the girl to give up her occupation. In two of the perfumes manufactured there were five possible skin irritants, one of which, linalool, a terpene alcohol obtained from the Mexican oil of linaloe, was found by the use of patch tests to be the probable cause of the dermatitis.

REPORT OF CASE

Mrs. A. D., aged 33, a white housewife, in May 1934 had an acute dermatitis involving the left subclavian and left mammary regions from the sternum to the extreme lateral margin of the chest. The condition began two and one-half weeks before consultation as an erythematous eruption which became vesicular in forty-eight hours. The onset was fairly sudden. Various simple home remedies had been used without any effect. The patient demanded relief from the annoying pruritus.

The previous history was negative for hay fever, asthma and urticaria. There was no history of drug idiosyncrasy either by ingestion or by local application. In March 1932 the patient had consulted me for a mycotic infection of the left hand, which disappeared following seven roentgen treatments.

The physical examination did not reveal any functional or organic disturbances. It is noteworthy that the entire skin was moist from perspiration. Examination of the urine gave negative results, and the red and white counts were normal. No focal infections could be determined in the teeth, tonsil or sinuses.

The condition immediately impressed me as being a dermatitis of external origin, and questioning on the first day brought out the fact that the husband was using two preparations on his hair, ointment (a proprietary medicated oil) and a sulphur-salicylic pomade. The possibility of an environmental dermatitis suggested itself and patch tests were made with these substances, but both were negative.

In spite of local soothing, astringent therapy, the eruption continued to spread. After repeated questioning on the second visit the patient stated that she had been using Emeraude

perfume daily for the past six months. A small quantity was sprayed on the dress over the left shoulder each evening. A patch test was immediately performed on the back with a Bloch 3 plus reading at the end of twenty-four hours (erythema and vesiculation). After discontinuance of the perfume the eruption entirely disappeared in five days. The perfume supplied by the patient was used as a patch test on four normal controls with negative results. No attempt was made to make patch tests on the patient with varying dilutions of the perfume.

COMMENT

Perfumes are complex products. The better ones on the market may contain as many as twenty-five ingredients in varying proportions, the exact formulas being carefully guarded trade secrets. It is difficult, therefore, to determine the specific sensitizing or irritating substance in the individual case. Most perfumes consist of (a) a coloring, (b) a fixative, (c) a solvent, (d) essential oils (fortifying) and (e) odor—animal, vegetable or synthetic.

According to Jausion,⁴ perfume dermatitis may result from sensitization to anilines or acetoaldehydes or from photosensitivity to the essential oils or to the coloring matter. There is usually an abnormal condition of the skin or what the French call the terrain, which acts as a predisposing factor. The conditions may be (1) previous sensitivity to other substances, (2) seborrheic dermatitis, (3) perspiration and (4) friction. In the case described, perspiration was an important factor, as the summer was abnormally hot in St. Louis.

DIAGNOSIS

The diagnosis of perfume dermatitis rests on careful questioning and on the clinical evaluation of the following points, which Hollander⁵ has stressed:

1 Location of the eruption. The bulk of the eruption will appear at the site of application (ears, nipples, chest, sides of neck or axillae). Generalization due to autosensitization occurs as the result of scratching or rubbing.

2 Sudden appearance. The onset is usually mild in hypersensitive individuals and severe if due to local irritant reaction.

3 Intense itching and burning. The intensity of these symptoms is usually out of proportion to the extent of the eruption and may be severe in neurotic patients.

4 Time element. According to Sulzberger and Kerr,⁶ eczematous sensitiveness consists of two periods of development: (a) the period of incubation or formation of sensitivity, which is extremely variable from months to years; and (b) the period of reaction time, which is usually constant and lasts from twenty-four to seventy-two hours.

5 Type of skin eruption. The berloque type of perfume dermatitis is usually linear and followed by pigmentation after exposure to sunlight. The contact type is at first localized over the site of application and may be erythematous or vesicular, depending on the degree of hypersensitiveness and the concentration of the antigen.

6 Diagnosis. The use of the patch test in skin testing is imperative in this type of case as the sensitization is epidermal. A square of white blotting paper 1 cm. by 1 cm. is saturated with the perfume to be tested and then applied to the skin over the back or over the V of the neck. The site is examined at the end of twenty-four, forty-eight and seventy-two hours to determine the degree of reaction.

7 History. Last but not least, incessant and repeated questioning is always necessary to elicit the facts. If cosmetic dermatitis is suspected the type and name of the various cosmetics, the frequency and time of use and the time of greatest intensity must be determined. In perfume dermatitis, the odor of the perfume that the patient is using should create suspicion.

CONCLUSIONS

Perfume may act as an eczematogenic agent under certain conditions and provoke a contact or eczematous dermatitis. Some cases of perfume dermatitis may be due to the fact that

certain batches may be more concentrated than usual, or irritants may develop in the perfume from age or from the action of light. Since most good perfumes are tested on the skin clinically by the manufacturers, the question of individual sensitization and preexisting changes in the skin rendering it more susceptible to damage must be considered. Once the cause is suspected the patch test is valuable in proving the diagnosis.

Without entering into a discussion of the antigen-antibody theory, it suffices to say that in the case reported there was a long incubation or refractory period of six months which finally ended with a cutaneous display of hypersensitivity (erythematous eruption). Repeated insult to the skin by the continuous use of the perfume finally produced an erythematous eruption, which in forty-eight hours became vesicular (reaction time). A threshold concentration of the perfume which was qualitative in nature, was necessary to change the clinical picture. Perfume dermatitis while more complex than that due to budesin picrate, corrosive mercuric chloride and other drugs, consists of the same vital processes and manifests itself according to similar principles of hypersensitivity.

DEATH FOLLOWING COAGULATION OF THE CERVIX

ROBERT I. HILLER, M.D., Milwaukee

From a survey of the literature one would gain the impression that coagulation and cauterization of the cervix were entirely harmless procedures. Yet I am aware of two deaths following cauterization of the cervix, reports of which have not as yet appeared in the literature. In one of these cases a retroperitoneal phlegmon and in the other a generalized peritonitis were found at autopsy. In 1928 Curtis¹ casually mentioned three cases of pelvic cellulitis from the use of cauterization treatment of the endocervix. All of his patients recovered. He felt that this complication was perhaps more common in those women who have a retrodisplacement of the uterus.

The two cases reported here emphasize the fact that coagulation of the cervix is not entirely without danger, especially if there has been a previous history of septic abortion.

REPORT OF CASES

CASE 1—History.—M. R., a white woman, aged 26, a waitress, was seen in consultation, Feb. 12, 1934, complaining of pain in the lower part of the abdomen. Nine days previously she had had a coagulation of the cervix with the Cherry electrode for about forty seconds. Following the coagulation she had experienced mild lower abdominal pains for about seven days. At the end of the seventh day the abdominal symptoms were aggravated and abdominal distention began to develop. She was admitted to the hospital on the following morning with a temperature of 100, pulse of 92 and a respiratory rate of 20. There were no symptoms referable to the urinary, cardiovascular, respiratory or central nervous systems. Except for mild constipation, requiring the regular use of magnesium magma, there were no symptoms of gastro-intestinal disturbances. The patient had begun to menstruate at 13. The periods were always irregular until she was 18. The flow lasted about seven days and was accompanied by dysmenorrhea on the first day. During the past three to four years the flow had lasted only two or three days. She had been married at 16 and gave birth to a child when she was 18. A few months after the birth of her child she again became pregnant and had a criminal abortion performed by a midwife. She became extremely ill with chills and fever and pain in the lower part of the abdomen and was confined to bed for several months. Two years before admission she began to have attacks of sharp pain in the left lower quadrant. These came at irregular times and were accompanied by a thick yellowish vaginal discharge varying in amount but never profuse enough to require the wearing of a napkin. At the age of 22 she was divorced. Her past history was devoid of other significant illnesses, operations or accidents. Measles had been suffered in childhood. Her mother, father and two sisters were all in good health.

Examination.—The blood pressure was 112 systolic, 70 diastolic. The pulse rate was 120. The temperature was 100 F. The respiration rate was 28. The patient was well developed and well nourished. She was acutely ill and pallid. No evidence of a pathologic condition in the lungs was found. The heart was rapid but no murmurs were detected. The abdomen was distended, and marked tenderness and muscle spasm was present over both lower quadrants. On vaginal examination, one could note infiltration in both broad ligaments as well as in the culdesac of Douglas. No bulging was noted at the first examination.

Both Wassermann and Kline tests were negative. The patient was a Moss type II. February 12 the hemoglobin was 93 per cent, the red blood cell count 4,780,000, the color index 0.9 plus and the white blood cell count 25,600, with 50 segmented and 45 nonsegmented polymorphonuclears, 3 lymphocytes and 2 monocytes. A blood culture taken on February 13 showed no growth after seven days.

Urinalysis, February 13, disclosed an acid, cloudy, dark amber urine with a specific gravity of 1.016, a trace of albumin and no sugar. A few leukocytes, an occasional granular cast and some squamous epithelial cells were found.

The impression gained was one of acute exacerbation of a chronic pelvic inflammatory disease, probably originating in an old postabortal infection.

Progress.—On the evening of the day of admission to the hospital the patient had a chill, after which her temperature rose to 105.2. This might have been accounted for in part by an intravenous infusion of dextrose and saline solution which she had obtained at noon. Her temperature thereafter fluctuated between 100 and 102.6. Dextrose and saline solution were administered intravenously almost daily and calcium gluconate was administered intramuscularly. The Levine tube was inserted for continuous gastric drainage, February 16, and left in place for two days. February 18, bulging was noted in the posterior vaginal vault and the entire vulva became edematous. Aspiration of the culdesac of Douglas yielded about 6 ounces (180 cc.) of thick gelatinous pus which on laboratory examination proved to contain gram-positive cocci in short chains—streptococci—gram-positive cocci in groups—staphylococci—and a few gram-negative bacilli. The patient's condition became progressively worse, presenting the characteristic picture of peritonitis, until death occurred, February 19.

CASE 2.—Mrs. G. H. was a well developed white woman, aged 22, who had had a criminal abortion performed a few years previously. She had no children. She could not recall the exact date of the abortion but estimated it to have been about three or four years previous to her present illness. In childhood she had had rheumatic fever following which a heart murmur developed. Since her abortion she had had pain in the lower part of the abdomen and on examination her physician had found an erosion of the cervix. He coagulated the cervix with a Cherry electrode, July 9, 1934. July 11 she began to have pain in the abdomen and was seen by me July 12 when she had a temperature of 100.4, pulse of 110 and presented marked tenderness in both lower abdominal quadrants. The rheumatic mitral condition was easily identified by the transverse hypertrophy of the heart and a rough systolic murmur at the apex. She was put to bed in Fowler's position with an ice bag to the lower part of the abdomen and nothing by mouth. By July 14 her temperature had returned to normal and the lower abdominal pain and tenderness had somewhat abated. She made an uneventful recovery.

COMMENT

In both of these cases a history of peritonitis following criminal abortion was present. In one case the abortion had been performed seven years prior to the cervical coagulation, and in the other at least three years. One might well be justified in questioning the possibility of organisms lying dormant in the tissues for such long periods in such a state as to be activated by the inflammatory process occasioned by a cervical coagulation. Curtis² expressed himself as follows on this point: Streptococcus infection of the tubes, as previously stated, is but part of a more widespread pelvic involvement.

¹ Curtis, A. H. Gonococcal Lesions of the Female Genitalia. *Am. J. Obst. & Gynec.* 10: 531 (Oct.) 1928.

² Curtis, A. H. Chronic Pelvic Infections. *Surg. Gynec. & Obst.* 42: 6 (Jan.) 1926.

The complete picture may, however, closely resemble gonorrheal disease. A history of abortion, a persistent tendency to aching distress in the pelvis, a prolonged tendency to slight chills or low grade fever are suggestive. The tissues may yield bacteria for a long period of time six months is fairly common, recovery of streptococci after two years is not infrequent, in one instance they were obtained eighteen years after the initial infection." The dormant bacteria, however, may possess varying degrees of potential virulence, since in the one case cited a fatal peritonitis resulted, whereas the other patient recovered. These cases further demonstrate that no lasting immunity need result from a previous peritoneal invasion.

CONCLUSIONS

A history of a septic abortion must be considered as a definite contraindication to coagulation treatment of the cervix.

GLANDULAR PHYSIOLOGY AND THERAPY

PREGNANCY TESTS

SELMAR ASCHEIM M.D.

Honorary Professor at the University of Berlin Honorary Corresponding Member of the Royal Society of Medicine London (Section of Obstetrics) Honorary Fellow of the Edinburgh Obstetrical Society

BERLIN

The old problem of the biologic diagnosis of pregnancy, that is, without physical examination of the woman, has practically been solved by the demonstration of the existence of certain hormones. No hormones are known, however, that appear solely and constantly during pregnancy, there are no specific hormones of pregnancy. Consequently there is no specific hor-

Fig 1—Ovary of infantile mouse (normal control) Numerous small follicles, no mature follicles

mone pregnancy reaction in the strict sense of the word. In human pregnancy there occurs so great an increase of certain hormones in the blood and so large an excretion of these hormones in the urine that, on the

In this translation from the German gonadotropic substance is employed as a generic term to indicate the gonad stimulating principle or principles of pregnancy blood or urine. The question as to whether this consists of one or of two factors has been discussed in the papers by Smith and by Collip. From the practical standpoint of pregnancy tests this makes little difference.—En

basis of this increased production and excretion, it is possible to diagnose pregnancy with the aid of animal experiments. The basis of the biologic pregnancy test therefore lies in quantitative and not in qualitative hormonal differentiation of the blood or urine of the pregnant woman as contrasted with the blood or urine of the nonpregnant woman. This difference is so exceptionally great that it may be considered the outstanding characteristic of the blood and urine in pregnancy.

Fig 2—Reaction 1 in ovary of infantile mouse. Large follicle with cavity and cumulus oophorus. This reaction is not adequate for the diagnosis of pregnancy.

There are two types of hormones that are definitely increased during pregnancy.

1 The estrus-producing hormone, which may be demonstrated by the Allen-Doisy test in the castrated mouse or rat.

2 The gonadotropic hormone, which is similar in its effects to the gonad-stimulating substance of the anterior lobe of the pituitary, this principle may be demonstrated (1) by the changes in the ovaries that result from its administration to the infantile mouse or rat, (2) by its effects on the endocrine function of the testicles of the infantile mouse or rat, or (3) by the changes produced in the ovaries of the mature rabbit.

The estrogenic substances are described more in detail in the article of Edgar Allen and the gonadotropic factors in the articles by P. E. Smith and by Collip.

During pregnancy the amount of estrogenic substance increases continuously, so that at about the fourth month it may be demonstrated in from 2 to 3 cc of serum or in 3 cc of urine by direct injection into test mice. During the latter months of pregnancy the amount of estrus-inducing principle increases markedly, especially in the urine, so that at this stage from 10,000 to 40,000 mouse units may be found in a liter of urine. In practice, biologic diagnosis of pregnancy is especially desired during the first few weeks, for this reason assay of estrogenic substance is not satisfactory for early diagnosis, but it may be an aid to diagnosis in the later months of pregnancy. Of seventy-five assays of urine from pregnant women during the first eight weeks, only seventeen showed a positive Allen-Doisy test with 4 cc of urine in the castrated mouse, twenty-five gave doubtful results, and thirty-three gave negative results. Furthermore, urine assays of many women afflicted with amenorrhea, some of whom had follicular cysts, gave positive Allen-Doisy tests with 4 cc of urine in the absence of pregnancy,

thus, assay of the estrus-inducing principle may be considered useless for the diagnosis of pregnancy.

In contrast are the rates of production and excretion of gonadotropic substance. Within a few days after the missed menstrual period it is present in the blood and is excreted in the urine in such amounts that a gonad-stimulating effect is demonstrable in from 1 to 3 cc of whole urine and even in smaller quantities of this fluid. The pregnancy test that I have developed is based on the assay of gonadotropic substance. The principle of the reaction consists in demonstration of the unusual increase of gonadotropic substance in the organism of the pregnant woman. As this substance is so abundantly excreted in the urine, the test consists in its detection in urine rather than in blood serum, the patient is thus not inconvenienced. The gonadotropic substance produces the same changes in the ovary of the infantile mouse as implantations or extracts of the anterior lobe of the pituitary, as Zondek and I, and P. E. Smith and Engle have demonstrated, a positive Allen-Doisy test may be obtained in from three to four days after the beginning of the experiment. However, estrus is not produced through the presence of estrogenic substance in the anterior hypophysis, as no effect occurs in castrated animals. This phenomenon is mediated by the changes produced in the ovaries of normal animals by an anterior pituitary gonadotropic factor.

In the ovary there appear (1) large mature follicles which on their part produce an estrogenic hormone (estrus is accordingly a secondary effect of the anterior pituitary factor), (2) numerous corpora lutea which either enclose the ovum or result from ruptured follicles, (3) large blood-containing follicles, especially in mice. On the basis of microscopic investigations we differentiate the following three reactions as the characteristic effects of gonadotropic substance on the ovaries of infantile mice.

1 Reaction 1 Follicular maturation, formation of large follicles with secondary estrus (figure 2, com-

Fig 3—Reaction 2 in ovary of an infantile mouse. Hemorrhage in enlarged follicles (blutpunkte). This reaction is used as a pregnancy test.

pare with figure 1, which represents the normal ovary of an infantile mouse).

2 Reaction 2 Hemorrhage in the follicles (German, "blutpunkte") (fig 3)

3 Reaction 3 Formation of corpora lutea with imprisonment of the ovum (fig 4)

The appearance of corpora lutea with enclosure of the ovum following administration of an extract of the

anterior pituitary was first discovered by Long and Evans. Reaction 1, the formation of mature follicles, presents a physiologic effect, reaction 2 and reaction 3 may be designated as pathologic reactions. Under appropriate experimental conditions certain corpora lutea may appear without enclosure of the ovum, following rupture of mature follicles, that is, the physiologic process of follicular maturation and rupture may be brought about by hormones of the anterior hypophysis.

Fig 4—Reaction 3 in ovary of infantile mouse. Corpora lutea (3) with enclosure of ovum, A (corpora lutea atretica). This reaction is likewise used as a pregnancy test.

The known fact that the anterior lobe of the hypophysis hypertrophies during pregnancy and the generally accepted thesis that this hypertrophy of the anterior lobe is a sign of increased function induced me to investigate whether or not the characteristic principles of the anterior lobe could be demonstrated in the organism of the pregnant woman by means of the aforementioned reactions. I found that implantation of placenta, decidua, corpus luteum of pregnancy and even ovarian cortex of pregnancy produced the same reaction in each case, injection of amniotic fluid or of embryonic extract was similarly effective. Most important of all was the demonstration that the serum of pregnant women contained gonadotropic substance having effects in the infantile mouse similar to those of extracts of the anterior hypophysis. The evidence apparently substantiated the thesis that gonad-stimulating substance appeared in the blood through increased activity of the pituitary itself. It appeared from my discovery, however, that the placenta was very rich in this substance, particularly in the early months of pregnancy, that this organ might also be involved in its production. Later it was found (Philipp) that implantation of the hypophyses of pregnant women into infantile animals had no effect on the ovaries of these animals. It appeared from these studies that the substance which we were able to demonstrate in pregnant women was not of hypophyseal origin but was produced in the placenta. The question is as yet not definitely decided, however, from the practical point of view it is not important for the pregnancy test.

After parturition, gonadotropic substance disappears from the blood stream within three days, at least it cannot be demonstrated after that period in 3 cc. of serum. This fact induced me to investigate what happened to this hormone in the body and whether or not it was excreted in the urine. After I had determined the excretion during the first few days of the puer-

perium I came to the amazing conclusion, on investigating further that gonadotropic substance is excreted in the urine of pregnant women in such large quantities that even as soon as four or five days following the expected onset of the missed menstrual period a positive reaction could be obtained in infantile mice with from 1 to 3 cc of urine. It immediately occurred to me that assay of gonadotropic substance in the urine presented a useful test for the diagnosis of pregnancy and in the large series of investigations that I conducted, originally in collaboration with Zondek, this assumption was completely substantiated.

Fig 5—Ovary of infantile mouse (normal control) magnified six times

In these investigations it was soon apparent that the effect designated as reaction 1 that is, the formation of large follicles with a secondary Allen-Doisy reaction, could also be demonstrated with the urine of women beginning the menopause or of those in the advanced climacteric, with the urine of castrated women and with that of

women with severe primary or secondary amenorrhea. Women with carcinoma of the uterus were found also to excrete follicular maturation substance, often in great amounts, I now believe on the basis of recent investigations that the fact that most of these women were in the menopause is more important than the fact that they were suffering from carcinoma.

Reaction 1 consequently does not serve as a satisfactory criterion of pregnancy. Definite criteria for the diagnosis of pregnancy are reaction 2 (blutpunkte) and reaction 3 (corpora lutea). Reaction 1 must also be evaluated, since occasionally it is the only reaction that occurs in early pregnancy. In such cases the test must be repeated, as far as I was able to determine, in actual pregnancy reactions 2 and 3 always occurred subsequently.

The technic of the reaction proposed by myself with a few slight modifications of the original method, is as follows. Five infantile mice are used for each test. The animals are weighed at the beginning of the experiment, they should weigh not less than 6 Gm nor more than 8 Gm. (Animals of this weight which we procure from dealers in Germany, are usually from 3 to 4 weeks old and show no spontaneous sexual maturation. In other stocks, previous investigation must be made as to the weight of the animals at puberty.) The first urine passed in the morning is injected into the animals subcutaneously, in six doses. Originally six doses of 0.2 cc, of 0.25 cc, of 0.3 cc (two animals) and of 0.4 cc were injected into each of five animals, respectively, during a period of thirty-six hours. For the sake of simplicity this procedure was modified so that six doses of 0.5 cc are injected into each of five animals, three doses on the first day and three on the second day. (Many urines are quite toxic. Some of these toxic urines, but not all of them, may be detoxicated by shaking them up with ether in accordance with the method proposed by Zondek.) On the fourth and fifth days, vaginal smears are made, ninety-six hours after the beginning of the test the animals

are killed and the ovaries examined for corpora lutea and blutpunkte. These may usually be seen with the naked eye but more readily with a lens (figs 5 and 6). A microscopic examination of the ovaries is seldom necessary. I make such examinations only to establish the occurrence of reaction 1 in case a positive Allen-Doisy test shows a definite hormone effect but the corpora lutea and hemorrhagic spots are not apparent. In such an event the urine is subjected to a second examination.

Positive results sometimes may be obtained as early as sixty hours after the first injection. In this case it is advisable to use several more animals and to kill only half of them at sixty hours. If a positive diagnosis is not made at this time, the result is checked with the remaining animals at ninety-six hours. In emergency cases the Friedman method, which employs mature rabbits may be used, with this method diagnoses may be made in twenty-four hours.

My own results in 2,000 control urine assays made on women with undisturbed normal pregnancy and on nonpregnant women were as follows:

Urine specimens of normal undisturbed pregnancy, 925
Positive reactions (2 and 3), 908, or 98 per cent
Negative reactions, 17, or 2 per cent

Of these seventeen cases, eleven showed reaction 1. Of these eleven cases, eight gave definite reactions 2 and 3 on the subsequent tests. Urines of the other three patients were not sent to the laboratory for further investigation, hence these could not be examined again. Therefore, false negative reactions were obtained in only six cases, or in 0.65 per cent of the cases of pregnancy.

Urine specimens from definitely nonpregnant women, 1,075
Negative, 1,070, or 99.5 per cent
Positive (2 and 3), 5, or 0.5 per cent
Results: 2,000 urine examinations with twenty-two mistakes, or 1.1 per cent.

False diagnoses, excluding the cases showing reaction 1 amounted to eleven cases, or 0.55 per cent. Seven

Fig 6—Ovary of mouse injected with pregnancy urine. (4) corpora lutea (2), positive pregnancy reaction (magnified six times)

hundred urine specimens were included that were taken from the fifth to the eighth week of pregnancy, of which the results of the test in fourteen were erroneous (2 per cent). Of these fourteen mistakes seven were corrected by the second test (namely those which gave reaction 1), so that for early pregnancy practically 99 per cent of the results were correct and 1 per cent erroneous.

Later investigators who worked with the original method reported 11,345 urine examinations up to 1933 with 211, or 1.8 per cent, false reports. These results deviate only slightly from my own. The reliability of this reaction, therefore, exceeds by far that of all other biologic pregnancy tests.

Before the application of this method to pathologic cases of pregnancy is discussed it is necessary to con-

questions: 1. How early in pregnancy does the reaction occur? 2. How long does it persist after termination of pregnancy?

Several cases have been reported in which a test made following the coitus resulting in pregnancy with a positive reaction was obtained before the onset of the expected subsequent menstrual period. Reaction 1 in such cases several times. A reaction was reported in one case ten days after coitus and in another case fourteen days after and in a case

Fig 7—Ovary of sexually mature virgin rabbit. Large and small follicles are visible neither follicles containing blood nor corpora lutea.

observed sixteen days after the coitus resulting in pregnancy. In view of the small number of cases and it is not possible to state exactly how many days after coitus resulting in pregnancy a positive reaction can first be obtained. Obviously a positive reaction can occur only when the trophoblast has entered the maternal circulation and exchange of material between it and the circulating blood has begun.

With the technic described gonadotropic substance can be detected in the urine beyond seven days after the birth of a full term child. The excretion lasts several days following abortions in the early months of pregnancy but this varies in individual cases, in general the action of gonad-stimulating substance ends by the third day but in some cases positive reactions may be obtained as late as the sixteenth day. Often before the reaction becomes completely negative, reaction 1 may be obtained.

Since the reaction depends on exchange of material between the uterine circulation and the chorionic epithelial tissue, it may be concluded in some cases that the reaction disappears after having previously been positive, biologic contact between ovum and trophoblast has been interrupted and the ovum has died. Caution of warning is necessary here. In cases of clinical pregnancy in which the hormone test has been made only once and has been found negative one cannot conclude from this single examination of the urine that the fetus has died, and interruption of pregnancy should never be considered on the basis of a single negative hormone test. In such a case repeated examinations of the urine—also of the blood serum—gonadotropic and estrogenic substances must be determined and all other methods for determining the viability of the fetus (roentgenogram, heart-beat and so on) must confirm the negative hormone tests. Even the most experienced gynecologists will leave expulsion of the fetus to nature.

What does the hormone pregnancy reaction offer to the diagnosis of extra-uterine pregnancy? The clinician speaks of ectopic pregnancy without considering

whether it is a matter of living and growing or of dying or dead extra-uterine pregnancy. The biologic reaction informs one primarily as to whether living chorionic epithelial tissue is to be found in the body. From positive reactions in cases clinically diagnosed as extra-uterine pregnancy one may conclude that either an intact and growing extra-uterine pregnancy or a pregnancy in which the fetus has died just recently is present, as in the case of dead intra-uterine pregnancy, gonadotropic substance continues to be excreted for a number of days. An absolutely negative reaction in extra-uterine pregnancy justifies the contention that the fetus no longer lives, that the villi no longer grow, and that the uterine vessels can no longer be eroded. Reaction 1, which is often found in extra-uterine pregnancy, supports the clinical diagnosis of this condition and makes it probable that the pregnancy has just ceased growing, in these cases with reaction 1 on first examination, later no reaction at all is obtained.

I consider it incorrect in statistics on extra-uterine pregnancy to state, for example, that of 100 cases of extra-uterine pregnancy so many cases gave a positive and so many cases a negative result and to conclude from this that the negative results are failures of the reaction. It is necessary to consider the clinical and the anatomic changes, from which it may be determined why, in a number of cases, the biologic reaction is negative or, better said, why it may no longer be positive. In connection with the clinical changes the hormone test, when it is negative or gives reaction 1, permits a diagnosis of dead or dying ectopic pregnancy. The following is a summary from my own material of results with urine specimens from 122 cases of clinically suspected extra-uterine pregnancy. Of these 122 cases operative interventions in sixty-six confirmed the diagnosis of extra-uterine pregnancy. Of these sixty-six cases, fifty-three showed reactions 2 and 3 and eight showed reaction 1. In the eight cases a dying extra-uterine fetus was present according to the anatomic observations. Five cases were completely negative in these the preparations showed the presence

Fig 8—Ovary of sexually mature virgin rabbit twenty hours after intravenous injection of 10 cc of urine from a pregnant woman. Follicles containing blood. Magnified seven times.

of an old tubular mole. In forty-nine cases in which differential diagnosis of extra-uterine pregnancy and tumors of the adnexa were necessary, the reaction was negative. Clinical examinations showed that these were not cases of extra-uterine pregnancy. Of the remaining seven cases, three showed a positive reaction 2 and 3, these were cases of intra-uterine pregnancy. Four showed reaction 1, in one of the latter there was a well founded suspicion that shortly before an abortion had

been performed, and in the three other cases this was similarly suspected but not definitely substantiated.

Professor Wagner has proposed the following valuable method for the differential diagnosis of inflammatory tumors of the adnexa with hemorrhage from the uterus and extra-uterine pregnancy with hemorrhage. The patient is given two injections daily of 1 cc of posterior pituitary extract. After from five to six days uterine hemorrhage arising from inflammation disappears, while in extra-uterine pregnancy the hemorrhage persists. A combination of this clinical method with the hormone pregnancy reaction provides a high degree of diagnostic accuracy in the differential diagnosis of extra-uterine pregnancy and inflammatory tumors of the adnexa.

In hydatid mole the pregnancy reaction has also proved quite valuable. As the reaction is positive in these cases it was thereby proved that this is independent of the fetus itself and dependent only on the presence of chorionic epithelium. In hydatid mole the quantity of gonadotropic substance produced often shows an exceptional rise. On an average, approximately 25,000 mouse units per liter of urine (urine collected in the morning) is found in the second to the third month of normal pregnancy. In hydatid mole, however, frequently amounts of several hundred thousand units are excreted per liter. The quantity excreted depends on the size of the hydatid mole. In small hydatid moles and in degenerated hydatid moles an increase above that found in pregnancy may not occur at all, indeed, in one case of hydatid mole that had been isolated from the uterine circulation by a fibrinous coating, no gonadotropic reaction could be obtained in the urine from this patient, although the tissue of the hydatid mole itself was effective on implantation (Philipp). If hydatid mole is suspected, quantitative evaluation of the urine should be undertaken. Values of more than 100,000 mouse units per liter point to the presence of hydatid mole with great probability. Such assays, however, do not give absolute surety, for in one case of twin pregnancy 100,000 mouse units per liter was observed. Recently I was able to demonstrate 100,000 mouse units on first examination in a pregnancy of three months' duration, whereas several weeks later a second examination showed a smaller value, at the termination of pregnancy a child was born with normal placenta. Furthermore, it may be said that hormone diagnosis does not permit one to dispense with clinical and physical methods of diagnosis.

In malignant chorionepithelioma the reaction has attained great significance, in this disease, large amounts of hormone are usually excreted. Clinically and histologically the diagnosis of this type of malignant tumor offers great difficulties. Tissue obtained by curettage frequently presents pictures that are highly suggestive but nevertheless cannot be designated by the investigator as definitely malignant. In such cases the biologic reaction is of great value. If it gives a negative result, malignant chorionepithelioma may be ruled out. In positive observations, however, a quantitative evaluation should be made, high hormone values, 100,000 mouse units or more, point to malignant chorionepithelioma. Since the latter frequently occurs after hydatid mole, it should be required that, in every case of hydatid mole, urine examinations should be continued after evacuation of the uterus until the reaction is negative. This may happen after from eight to ten

days, indeed, excretion of gonadotropic substance may be found as late as two months afterward without implying the presence of a malignant tumor. It need not be especially emphasized that in the latter cases the most careful clinical observation is necessary and that in hemorrhages immediate curettage is advisable. If the reaction is at first negative and some time later a positive reaction sets in, this points to a malignant change in a hydatid mole, provided of course that pregnancy has not occurred in the meantime. After a chorionepithelioma has been removed, the recurrence of a positive reaction indicates the presence of metastases.

In this connection it is necessary to point out that other tumors with chorionic epithelial constituents also exist and that these give a positive reaction. Such tumors, mainly teratomas, are found in both men and women, especially in the generative glands. The clinician should be aware of this, so that he may not be led to a false diagnosis through a positive pregnancy reaction in one of those unusual cases of ovarian teratoma with chorionepithelioma. Furthermore, it may be mentioned at this point that many diseases of the hypophysis may show positive gonadotropic reactions. Pregnancy ordinarily does not complicate such cases, they are mentioned because they show why this test is not designated a reaction specific for pregnancy.

Of the numerous modifications of the method, such as the use of male infantile animals or the use of adult mice or rats, not one has any special advantage or has been generally employed, with but one exception, that is the valuable and important method of Friedman (of the United States) in which gonadotropic substance is demonstrated by means of mature female rabbits. The method is based on the fact that, like extracts of the anterior hypophysis, pregnancy urine causes rupture of mature follicles (which are almost constantly present in mature female rabbits) in from sixteen to twenty-four hours. This is therefore a satisfactory and rapid biologic indicator of pregnancy.

The technic has been practiced by most investigators in the following manner. Ten cubic centimeters of urine is injected into an ear vein of a mature female rabbit, which must have been isolated for at least three weeks previously. The ovaries are examined twenty-four hours later. The reaction is positive if the follicular rupture is marked by a reddish protrusion or by recent hemorrhage in the follicles. According to the literature, the reaction has the same reliability as the original method in infantile mice. I employ it when, as in tubular pregnancy, a rapid diagnosis is necessary, and I regard it as a valuable complement to the original method. It is not a complete substitute for the latter, since one cannot determine the occurrence of reaction 1 by the Friedman method. Frequently I have had a negative result with one rabbit while in mice reaction 1 occurred, without the parallel mouse experiments, false negatives would have been reported. In these cases I repeated the urine tests and was able to make the correct diagnosis. In extra-uterine pregnancy, I consider the rabbit reaction of unusual value because with this method many patients can be operated on from two to three days earlier. In case of freshly ruptured extra-uterine pregnancy no biologic reaction is needed since this type of pregnancy with signs of internal hemorrhage must be brought to operation immediately.

I cannot at this point delve into the question of whether there are one or two gonadotropic substances

Of the other animals, only the higher apes, for example, the orang-utan, show this urine reaction. In pregnant mares gonadotropic substance is found in abundant quantities in the blood during the first month of pregnancy, as Cole and Hart (of the United States) have determined. After that time it is no longer demonstrable. The pregnant mare excretes unusually large amounts of estrogenic substance especially during the second half of pregnancy. This fact has been applied by Kust and Gravert to the diagnosis of pregnancy. This method has also been verified by Crew of Edinburgh and by Zondek.

The discussion presented here is intended to acquaint the practitioner with the nature and reliability of the hormone pregnancy reaction so that he may make use of it in conjunction with clinical observations in the diagnosis of pregnancy.¹

LEAGUE OF NATIONS INVESTIGATION AND REPORT ON TREATMENT OF EARLY SYPHILIS

By THE COMMITTEE OF EXPERTS ON SYPHILIS AND
COGNATE SUBJECTS, ZURICH NOV 21-23 1934

The Health Organization of the League of Nations publishes¹ the results of an inquiry into the treatment of syphilis carried out in five countries (Denmark, France, Germany, Great Britain and the United States), ninety-three clinics in these countries have contributed to this inquiry and 13,198 case records of primary and secondary syphilis have been analyzed.

Guided by the principles revealed by the study of these records the experts who have collaborated² have adopted the following recommendations which are of great interest to syphilologists, public health officers and private practitioners.

1 Treatment should be recommended as early as possible in the seronegative primary stage. In this connection, the fullest possible use should be made, for purposes of diagnosis, of the microscopic examination of secretion from primary lesions or from lymph glands.

2 It should be emphasized that, prior to the institution of either of the systems of treatment to be outlined, there should be an adequate physical examination to determine the absence or otherwise of any indication for caution in respect of the dosage.

3 It is essential that, in carrying out the treatment, a strict supervision of the patient be exercised especially in respect of the mucous membranes, skin, kidneys and liver.

4 Observations, clinical and serologic, after completion of treatment should be adequate and in any case for not less than three years.

5 Adequate examination of the spinal fluid, at least before dismissal from observation, is essential.

6 The principles to be followed in carrying out the actual treatment should be as follows:

(a) To employ a comparatively heavy individual dosage of the arsphenamines and of the bismuth or mercurial compounds, the doses being administered in comparatively rapid succession, especially at the commencement.

(b) To maintain a persistent attack on the disease, avoiding intervals of such length as to afford the parasite an opportunity of recovering.

(c) To administer approximately as much treatment in primary as in secondary cases.

7 The material studied does not enable a clear decision to be made as to the relative merits of intermittent treatment, with courses of injections in rapid succession separated by rest intervals of some weeks, and continuous treatment, or between the simultaneous employment of both arsenical and bismuth or mercury and the system in which bismuth and mercury are withheld until a number of arsenical injections have been administered.

Nevertheless it seems practicable from the results of the analysis and from the personal experience of the experts to formulate a system of intermittent treatment.

TABLE 1—Plan of Courses of Injections

Week	Neocars phenamloe Gm	or	Ars phenamloe Gm	and	Insoluble Compound of Bismuth Coccalnlog Bismuth Metal * Gm
1st	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
2d	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
3d	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
4th	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
5th	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
6th	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
7th	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
8th	0.0 to 0.75	or	0.4 to 0.5	and	0.20 to 0.24
9th					0.20 to 0.24
10th					0.20 to 0.24

* By insoluble bismuth is here meant compounds of a very slight solubility to water. They should therefore be given in suspension those of extremely slight solubility (the oxychloride, etc.) usually in a watery suspension those that are more soluble (the subsalicylate, quinine bismuth iodide, the alkaline tartrates, etc.) suspended in a vegetable oil. If a liposoluble compound (e.g. the camphocarboxylate, etc.) is preferred it is desirable that the injection be given twice weekly in half doses.

The dosage of all bismuth compounds should be calculated according to their content to bismuth metal.

As an alternative to bismuth a course of mercury may be given either in the form of injections (40 days at 3 Gm. of unguentum hydrargyri) or of injections (70 mg. of mild mercurous chloride or 120 milligrams of mercuric salicylate, etc. suspended in a suitable base).

and one of continuous treatment either of which can be expected to yield satisfactory results in ordinary cases of early syphilis.

It seems possible that the intermittent treatment that is suggested may in effect be continuous or practically continuous treatment owing to the continued absorption of bismuth from the sites of the injection for some weeks after any temporary suspension of the treatment.

PLAN OF INTERMITTENT TREATMENT

For adult males of average weight less than 50 years of age and in whom there is no contraindication, a number of courses of injections on the plan described. It should be said that, at the beginning of this course, some administer at once the full weekly dose (from 0.60 to 0.75 Gm.), while others divide it into two doses (e.g., 0.30 and 0.45 Gm.) so far as the first week is concerned.

1 Further discussion of this subject may be found in Aschheim Selmar Schwangerschaftsdiagnose aus dem Harn ed 2 Berlin S Karger 1933

Clauberg Die biologische Frühdiagnose der Schwangerschaft (AZR) Review in Ber u d ges Gynak u Geburtsh 25 No 4/5 1933 Engle E T in Allen Edgar Sex and Internal Secretions Baltimore Williams & Wilkins Company 1932 chapter XVI

1 Quarterly Bulletin of the Health Organization 4 March 1935

2 Prof J Jadassohn former director of the dermatologic clinic of the University of Breslau Col L W Harrison technical adviser in venereal diseases Ministry of Health London Prof T Madsen director of the state serotherapeutic institute Copenhagen Prof Louis Queyrat President of the Ligue nationale française contre le peril vénérien Professor Queyrat died and was succeeded by Prof H Gougerot director of the Clinique des maladies cutanées et syphilitiques de la Faculté de médecine de Paris (Hôpital St Louis) Prof C Rasch director of the State Hospital Copenhagen whose place was occasionally taken by Dr Svend Lomholt director of the dermatologic clinic of Finsens Lysinstitut Copenhagen Dr John H Stokes professor of dermatology and syphilology University of Pennsylvania School of Medicine Philadelphia Rapporteur consultant in venereal diseases United States Public Health Service Prof Hans Martenstein director of the dermatologic clinic Municipal Hospital Dresden Friedrichstadt.

It is recommended that

(a) In cases which remain or become serologically negative during, or by the end of, the first course four such courses be administered, with intervals of three to five weeks between any two courses

(b) In cases which have not become seronegative by the end of the first course, in addition to the amount of treatment shown in *a*, further courses should be administered until the patient has received as a minimum three beyond that which has ended with negative serum reactions. At the option of the individual clinician, this treatment may be prolonged as may be considered necessary

and the arsenical, believed by some observers to protect against neurorelapses, one should begin the bismuth treatment two, three or even four injections before the end of the longer arsenical course and continue it through the period in which the arsenical is suspended and on into the beginning of the next arsenical course. The bismuth treatment is then suspended while the arsenical course is completed

The bismuth salt advised for this system is bismuth salicylate in oil suspension, in full adult dosage with due regard for weight. Other preparations of bismuth may be used only with due regard for an equivalent metallic content and for their rate of elimination. The

55	0.4			
56	0.4			
57	0.4			
58	0.4			
59	0.4		1	It is safer to finish treatment with bismuth or mercury compound rather than with arsphenamine.
60-69		Bismuth compounds 10 doses or mercurial ointment and potassium iodide		
70-122	Probation	No treatment	6-12	Complete physical and neurologic examination, lumbar puncture and if possible fluoroscopic examination of heart and great vessels.
123	Complete			

(c) Cases presenting signs of clinical relapse of an early type should be dealt with on principles similar to those enunciated in *b*.

For nonpregnant females treatment should be administered on the plan outlined for men, with the exception that the single dose of neoarsphenamine should be reduced by 0.15 Gm and that of arsphenamine by 0.1 Gm.

In the event of any reduction in the amount of treatment being indicated, it is recommended that this be effected by reducing the number of arsenical injections rather than by reducing the individual dose or increasing the intervals.

As an optional scheme more in harmony with the trend toward longer courses, three series of from ten to twelve injections each of the arsenical drugs may be given. To secure an overlapping of the heavy metal

mercurial injection is 50 per cent metallic mercury in a suitable fatty base, the dose being 4 Gm by injection, from five to six injections each week. The use of the iodide is optional, depending on indications.

The use of insoluble mercurials intramuscularly in this system is not recommended.

It should be further understood that when heavy metal is employed after the last course of arsphenamine the heavy metal courses are to be separated by rest intervals of from six to eight weeks after each series of ten weeks injections, or each course of forty injections.

In cases of primary syphilis that have remained seronegative throughout, a minimum of five courses of arsphenamine or neoarsphenamine should be given. In cases of seropositive primary syphilis, the full treatment called for by this system should be given.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR FEDERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG Secretary

WARRANTY SWEET BEETS

Manufacturer—The Nielsen Corporation Ltd. Oakland, Calif.

Description—Sliced beets prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacture—The beets as received from the field are cooked in steam to loosen the skins which are removed by hand. Any necessary trimming is done at the same time. After a final rinse, the beets are cut and ground and subsequently processed and canned by essentially the same procedure as described for Warranty Sliced Spinach (*THE JOURNAL*, Feb 2 1935, p 399).

Analysis (submitted by manufacturer) —	per cent
Moisture	87.8
Total solids	12.2
Ash	0.8
Sodium chloride	0.05
Fat (ether extract)	0.02
Protein (N X 6.25)	1.3
Reducing sugars as invert sugar	0.6
Sucrose	6.5
Crude fiber	0.6
Carbohydrates other than crude fiber (by difference)	9.5

Calories—0.4 per gram 11 per ounce

Vitamins—The method of preparation and processing insures the retention in high degree of the natural vitamin values.

Claims of Manufacturer—Specially intended for infants, children and convalescents, and for special smooth diets. Only warming is required for serving.

SPECIAL DRICO

Manufacturer—The Dry Milk Company, Inc., New York.

Description—Drum dried irradiated partially defatted milk (Dryco) fortified with vitamin B concentrate prepared from rice polish. Contains from 100 to 125 Sherman vitamin B units per ounce.

Manufacture—Rice 'polish' is extracted with moderately warm water. Insoluble matter is mechanically separated out of the filtrate. The almost clear filtrate is dried and stored either in air tight containers or hermetically sealed containers filled with inert gas, or is concentrated to a viscous syrup and stored at a low temperature (—20 C). The vitamin B concentrate, either in dry or in syrup form, is added to the irradiated fluid milk prepared as previously described for Drico (*THE JOURNAL*, Jan 2 1932 p 49) in the proportions of 3.5 parts of solids of the rice polish extract to 96.5 parts of milk solids. The mixture is dried by the Just process, as previously described for Dryco, and hermetically sealed in cans in the presence of nitrogen gas.

Analysis (submitted by manufacturer) —	per cent
Moisture	3.1
Ash	7.0
Fat (ether extract)	11.6
Protein (N X 6.25)	31.5
Carbohydrates (by difference)	46.8

Calories—4.2 per gram 119 per ounce

Vitamins—Contains from 100 to 125 Sherman vitamin B units and from 37 to 52 U S P vitamin D units per ounce. Taken as a daily ration, it prevents rickets.

Claims of Manufacturer—Especially recommended for infants deprived of mother's milk and for convalescents.

SURE HIT BRAND CRUSHED HAWAIIAN PINEAPPLE (STANDARD QUALITY)

Distributor—Alexander & Baldwin, Ltd., Honolulu, Hawaii.

Packers—Kauai Pineapple Company, Kalaheo, Kauai; Baldwin Packers Ltd., Lahaina, Maui, and the Maui Pineapple Company, Kahului, Maui (subsidiaries).

Description—(1) and (3) Grades of crushed pineapple packed in pineapple juice with added sucrose. (2) Crushed pineapple packed in pineapple juice without added sucrose.

Manufacture—Crushed pineapple obtained by shaving off the flesh adhering to the skins or by the mechanical cutting of broken slices is cooked in steam jacketed kettles with or without the addition of sucrose, and is canned and processed. The distinction between the grades is that of added sucrose only.

Analyses (submitted by distributor) —

Fancy finest quality in juice 0.6 per gram 17 per ounce.
Standard quality in syrup 0.8 per gram 23 per ounce.

Vitamins—Biologic assay shows the products to be a good source of vitamins A, B and C containing only slightly less than fresh pineapple.

HERCULES JUSTRITE BRAND GELATIN TITAN JUSTRITE BRAND GELATIN

Distributor—Meyer-Blanke Company, St. Louis.

Packer—Atlantic Gelatin Company, Inc., Woburn, Mass.

Description—Granular and flake plain unsweetened, unflavored gelatins, graded on the basis of jelly strength for special uses, the same as Atlantic Super-Clarified Gelatin (*THE JOURNAL*, Feb 18, 1933 p 499).

RIVAL UNSWEETENED EVAPORATED MILK

Distributor—Rival Foods Inc., Cambridge, Mass.

Packer—Sheffield Condensed Milk Company, New York.

Description—Canned unsweetened sterilized evaporated milk, the same as Sheffield Select Brand Unsweetened Evaporated Milk (*THE JOURNAL*, Feb 3, 1934, p 373).

FOOD POISONING

Food poisoning has recently become the object of much discussion and experimental investigation. This increased interest may be the result of a newly awakened consciousness that many mild intestinal upsets are due to some toxic bacterial substance. Interest has been stimulated and knowledge increased especially by the work of E. O. Jordan, a pioneer in the field. Food poisoning, in the sense used here, is characterized by diarrhea, nausea, abdominal pains and sometimes fever, which result from the ingestion of foods contaminated with bacteria or their products. The onset is from two to twenty-four or thirty-six hours after eating, and the attacks vary in severity. Usually they are not of long duration and recovery is complete. Botulism, of course, has a distinct and different clinical syndrome, the primary symptoms are great muscular weakness, no fever, profuse secretions from both the mouth and the nose, and often disorders of the eyes. Botulism is not difficult to diagnose and the mortality is high. It is the result of the ingestion of a true toxin from food contaminated with *Clostridium botulinum*. Patients show symptoms of a profound systemic toxemia rather than the gastro-enteric irritation characteristic of the food poisoning under consideration. The cases of so-called ptomaine poisoning are in all probability forms of food poisoning due to toxic substances other than ptomaines.

For many years, members of the *Salmonella* group have been regarded as the most important agents of acute food poisoning other than botulism. Recently, however, Jordan's work¹ has brought proof that other bacteria are implicated. Progress with this investigation has been retarded by the nature of the problem. Often the causative agent must be sought in a remote bakery, canning company or other food concern. The only clue available for the investigator is what he sees in those affected. By a process of selection and elimination he determines what food from a common source the patients have consumed. Not infrequently the contamination may occur in bakeries, bacteria having been

isolated from fillings for cakes and pies. *Staphylococci*, and more particularly *Staphylococcus aureus*, have been isolated as the active agents in a number of outbreaks. Occasionally streptococci also have been found. The symptoms in these cases vary to some extent from those of *Salmonella* poisoning. The incubation period is shorter and, while the symptoms are acute and sometimes alarming, the mortality is low.

The toxic substance causing certain food poisonings is a product of bacterial metabolism. The first successful experiments to establish this fact are described by Dack,² who fed bacteria-free filtrates of *staphylococcus* cultures to human volunteers and obtained symptoms of typical food poisoning. Jordan and McBroom³ in 1932 made successful experiments in several species of juvenile South American monkeys. They fed the animals approximately 50 cc of a filtrate of cultures of *staphylococci* isolated from patients with food poisoning. Diarrhea, loss of appetite and abdominal distress developed. Of thirteen animals infected, definite symptoms were obtained in five. A possible explanation of this small number of takes has been proffered by Borthwick,⁴ who states that the p_H has a definite and strong effect on the active principle in toxic filtrates of *staphylococcus* cultures, the toxicity being destroyed or markedly decreased at a p_H higher than 7.8 or lower than 6.8. He succeeded in producing symptoms in guinea-pigs without exception by adjusting the stomach reaction to a p_H favorable for the action of the poison (7.3) before feeding *staphylococcus* filtrates to the animals. Differences of the p_H of the stomach contents may afford an explanation, then, for the variable results in attempts to reproduce the symptoms in animals.

Staphylococcus products are not the only substances to be considered in food poisoning. In a recent epidemic in Winona a green-producing streptococcus was isolated as the causative agent.⁵ Twenty-five cubic centimeters of a sterile filtrate of a culture of this organism, when fed to monkeys, caused symptoms identical with those caused by *staphylococcus* filtrates.⁶ The chemical nature of the toxic substance has not yet been clearly defined nor has it been demonstrated to be a true toxin. It appears to be similar in *staphylococcus* and *streptococcus* filtrates and is not limited to strains obtained in cases of food poisoning. Filtrates from *streptococcus* cultures of both alpha and beta types and from different origins are capable of causing food poisoning. Indeed, the presence of this poison may account for the gastro-intestinal symptoms in scar-

let fever and other streptococcic infections.⁷ Further investigation is necessary to ascertain the exact chemical nature of the toxic substance. It is extracted by ether⁸ is unstable when heated with hundredth normal hydrochloric acid, does not produce a positive skin reaction, and its effect is destroyed after cultivation of the organism for several generations on artificial mediums.

A knowledge of food poisoning is of importance to the student of public health and to physicians. An accurate recognition of symptoms and prompt report of cases will be of great value in the control of outbreaks. These recent investigations have advanced knowledge of food poisoning and are paving the way to the ultimate control and eventual elimination of the disease.

WATER TRANSMISSION OF AMEBIASIS

Evidence that amebiasis may be water borne has recently become highly suggestive. As a result of the outbreak of amebic dysentery in Chicago in 1933 cross connections between water and sewer lines and defective piping have been, as pointed out by Magath¹ and others, the source of surprising discoveries. Thus as he says, direct and indirect cross connections between sewerage and water lines is so common that one might say it is universal. The existence of this situation and the belief that massive doses of amebias are usually necessary for the development of human acute amebic infection, strongly suggest the water spread of most acute amebiasis.

Further evidence of water-borne amebiasis is offered in the recent report by Hardy and Spector.² Following an extensive fire in Chicago in May 1934 many cases of acute diarrhea appeared followed in due time by typhoid. These occurred in both firemen and spectators. As a result, a careful study of the water system in the fire area was undertaken. A double water supply, partly from private sources and partly municipal, was discovered. Moreover, open cross connections allowing the mixture of heavily polluted water with the city supply were later disclosed. It was thus apparent that most firemen as well as spectators in the immediate neighborhood of the fire were exposed to heavy pollution of their drinking water.

On the third and fourth days after the fire, acute enteritis among firemen was reported. That amebic dysentery might also be present seemed a distinct possibility and hence a special study was instituted. Classic cases were not, however, encountered among firemen.

2 Hardy A V and Spector Bertha Kaplan. The Occurrence of Infections with *E. Histolytica* Associated with Water Borne Epidemic Diseases. *Pub Health Rep* 50: 323 (March 8) 1935.

The early onset and course was not that of amebic dysentery, but later clinical and laboratory observations demanded its consideration. This evidence may be summarized as follows. *Endamoeba histolytica* was present in almost two thirds on one stool examination only. Bacteriologic studies failed to reveal other etiologic agents. Treatment with carbarsone was found to be remarkably effective. The late symptoms and course of the illnesses were quite characteristic of amebic infections. The authors therefore believe that *Endamoeba histolytica* was the important etiologic agent in the group with the more severe infections.

The investigation of firemen was paralleled by careful observations in all cases of amebic dysentery reported to the Chicago board of health. Routine information as to possible exposure at the stockyards fire was requested. Eleven cases apparently from this source were discovered. In five of these the laboratory examination pointed to a diagnosis of amebic dysentery, but on clinical grounds the illnesses could not be differentiated from nonspecific enteritis. The remaining cases were of unquestionable amebic origin.

The authors believe that these studies provide definite evidence that amebic dysentery may be water borne. Undoubtedly a large number of amebic infections resulted from drinking polluted water at the fire. There were, however, few cases of classic amebic dysentery. The explanation for this apparent paradox, they feel, lies in the probable association of acute nonspecific enteritis due to massive sewage ingestion with *Endamoeba histolytica* infestation.

OAKLAND COUNTY, MICH., MEDICAL EMERGENCY RELIEF

The cooperation of physicians, dentists, nurses and druggists in the County Emergency Welfare Administration in Oakland County, Mich., has resulted in a system of medical care for relief clients so comprehensive and satisfactory to all served that its description may be helpful to other localities. The plan is based on a faithful adherence to the intent as well as to the wording of FERA Rules and Regulations No. 7, in the preparation of which, it will be remembered, the American Medical Association participated. A "medical manual" has been issued, containing a description of the plan, all the blanks used, and standard instructions for all those concerned. In the introduction the medical director states that "the reason why we feel that this plan is successful thus far is the utter lack or absence of complaints from the welfare clients, and the universal approval of physicians and dentists."

Among the principles set forth as necessary to "be considered before any medical plan will function properly" are free choice of physician, cooperation of the county medical society, prompt payment for services rendered, no dictation of methods of treatment by law.

men, and a medical advisory committee that can and will discipline the members of the profession more effectively than others outside the profession

A characteristic of this plan, which is a deviation from the practice common elsewhere in emergency relief, is that any person who presents to any physician a card stating that he is on relief is immediately given the medical care needed. The physician reports the service furnished within seven days and receives payment usually within thirty days. This procedure places more responsibility on the physician and secures quicker action than when medical service must always follow a social service investigation. It also does away with any possible influence by a social service worker in the selection of a physician.

The spirit of the understanding is expressed in the statement that "social problems are one thing and medical problems another, and it would seem that by tending strictly to their own field both groups would be fairly well occupied during such times as these."

The medical work is under the direct supervision of a medical director who is a physician. It is made clear that the medical director "should serve in an administrative capacity entirely. It should not be his duty to dictate what diagnosis is made by the family physician or to criticize in any manner the type of treatment without first consulting the advisory committee appointed by the county medical society. In other words, he should refrain from medical dictatorship."

All disputes as to medical matters go before the medical advisory committee of the county medical society. There are special regulations to prevent imposition by clients who demand excessive medical service.

The fee schedule which "is intended as a guide only," is about one half of the minimum fees usually charged in the community. All drugs must be prescribed by the physician and must be taken from the U S P or N F unless special authorization is granted. Except in case of emergency, serious operations require consultation and special authorization. The arrangements as to dental care are practically the same as those for medical service. Nursing, surgical appliances, glasses, special diets and other things considered necessary by the attending physician are provided, also after special authorization.

The cost of the plan has been less than under previous methods of giving relief. In 1934 a total "gross case load" of 15,548 families was given medical care. This case load varied from 5,983 in June to 10,566 in December. The average cost for medical service for 1934 per family per month was \$0.9523 and the average cost per person was \$0.2506. The total payments to physicians for the year were \$89,729.74 and the total cost for all kinds of medical, dental, nursing and other service, excluding drugs and glasses, for which the audit is not yet complete, was \$116,881.06. Laboratory service was furnished by the

county hospital without charge. A letter signed by the board of directors of the Oakland County Medical Society says "We feel that the administration of medical poor relief in Oakland County has come as close to approximating the ideal as it is possible to come in the first year of any program."

Current Comment

YELLOW FEVER

Public Health Reports, issued weekly by the United States Public Health Service, contains current information regarding the prevalence and geographic distribution of communicable diseases in the United States as far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever and other important communicable diseases throughout the world. An excellent summary of the occurrence of yellow fever and the recent advances in knowledge relating to this disease¹ has just been made available. The incidence of yellow fever in Colombia and in West Africa is discussed, and the present status of this disease in the Americas is outlined. Although yellow fever is no longer a problem as a communicable disease in the United States, the report serves to emphasize the sporadic outbreaks that have occurred in other countries within the immediate past. Protection tests, transmission of protective qualities to offspring, dengue, vaccination and immunization are other topics considered in this report.

INHERITANCE OF PIGMENTATION

The question is constantly asked whether or not parents who are light in color, that is, one of whom has a small amount of Negro blood, may give birth to a coal-black child. Indeed, newspaper stories of the birth of a black child to white parents whose ancestry shows a slight trace of Negro blood several generations back appear with amazing frequency. The question is also asked whether or not pure Negro children may be born to mulatto parents who occasionally pass as white. The answer is of course in the negative. The entire subject was analyzed by Irene Barnes,¹ who was concerned particularly with the question whether or not the crossing of persons of different color results in a blend of pigmentation. In making her study, a technique for measurement of pigmentation was worked out and the previous literature on the subject was analyzed. Studies were then made on a considerable number of Negroes and the data obtained were compared with those available from previous studies. The conclusions were reached that the offspring of parents of different color tend to resemble the parent with the greater percentage of dark pigmentary supply more than they tend to resemble the parent with the less percentage. However, pigmentation is not inherited by blending nor is

¹ Yellow Fever. *Pub. Health Rep.* 50:369 (March) 1935.
¹ Barnes, Irene. *The Inheritance of Pigmentation in the American Negro*. *Human Biology* 1:321 (Sept.) 1929.

it produced by the action of one or two factors that act as mendelian dominants. The studies made by the Dravenports indicate that two nearly white hybrid parents can have offspring somewhat darker than themselves but that it is not genetically possible for nonhybrid parents to have Negro children unless a melanic mutation should occur. There is no evidence that such mutations do occur, and the appearance of a Negro child from a white parent naturally has a much simpler explanation.

Medical Economics

INFLUENCE OF SICKNESS INSURANCE ON DIPHTHERIA MORBIDITY AND MORTALITY

Diphtheria morbidity and mortality rates seem to offer a fairly sound test of the quality of medical service received by a community. The conquest of diphtheria is now in process. The methods of achieving victory are known. The date of complete triumph depends on the way in which these methods are applied to the entire population. Diphtheria death rates vary directly with the extent to which these known and tested methods of prevention and treatment are made available to the population. This situation furnishes conditions, almost labora-

ever to the existence of insurance, unless it is a negative relation. The number of cases has increased in Germany and Austria, where the insurance system extends to the family, and also in England and Wales, where families are not included. The number of cases has declined most rapidly in Canada and the United States, where there is no sickness insurance.

Promptness of treatment with immediate application of recognized remedies determines the mortality. The statistics on mortality are available only in a somewhat different form from those on morbidity. These statistics are given in table 3.

Again it is noted that the rate of decline in mortality is more rapid in the English and Scottish towns, where children are not included in the insurance system, than in Germany, where they are included. But the most striking fact is that in neither of these countries has the decline been as rapid as in the United States, with no insurance. These figures for the

tory in type, from which to determine the social value of a medical service.

The arguments for sickness insurance may be summed up in the claim that it removes the economic obstacles to the giving of medical service and thereby secures a wider and more effective distribution of that service. Because of the interest in the progress of this conquest of diphtheria, statistics have been gathered throughout most modern nations.

TABLE 2—Population According to Latest Available Information

	(1933)	(1931)	(1934 estimated)
Germany	65,013,082		
England and Wales	39,947,931

Czechoslovakia	14,726,158		
Canada	10,370,780		
United States	126,654,000		

The League of Nations has assembled the reported diphtheria cases from 1923 to 1933 for a number of countries. These are given in table 1.

The population of these countries, according to the latest available information, is given in table 2. It is at once evident from this table that variations in the number of cases between countries or in time within any country bear no relation what-

ever to the existence of insurance, unless it is a negative relation. This country and Canada, unencumbered by insurance, are the only ones in which there seems to be a possibility of complete victory. In 1933 the following eleven cities of considerable size had no diphtheria deaths: Duluth, Elizabeth, Hartford, Rochester, Salt Lake City, Seattle, South Bend, Spokane, Springfield, Syracuse, Yonkers. Some of the very largest cities in the United States had death rates much less than even the low average. Some of these and their death rates per hundred thousand in 1933 were as follows: Philadelphia, 0.7; New York, 1.2; Baltimore, 0.7; Chicago, 0.2; Milwaukee, 0.8; Omaha, 0.9; St. Paul, 1.1; Minneapolis, 1.4; Oakland, 0.7; San Francisco, 1.2.

Judging by these facts, the conclusion seems inevitable that the very classes for which insurance is proposed are now receiving under a system of private medical practice, in the United States and Canada, medical care far superior to that which is supplied when the same classes are put under an insurance system.

That this conclusion is justified is also the opinion of the observers in countries now having insurance. Edwin H. T. Nash, public health official of England, in discussing "The Present Position of Diphtheria Immunization" in the *Journal of State Medicine*, September 1934, pages 522 to 526, says:

At long last this country is really waking up to the importance and safety of immunization against diphtheria.

America has been some ten years ahead of us in this matter due to a certain extent to the American flair for wholesale publicity together with a more polyglot population in its big towns that is more susceptible to flamboyant methods of propaganda than our more sober-minded and less emotional people.

As a contrast compare London with 1 per cent of its school population immunized with New York State where the numbers immunized exceed 700 000. We have no figures in this country that can compare with those on the other side of the Atlantic. None of us who are immunizing on a larger scale here can approach the figures in some of the American towns where diphtheria is being steadily eliminated. Take Hamilton, Ontario.

In 1922 there were 32 deaths from diphtheria when immunizing was begun.

In 1925 the deaths had dropped to 14, in 1929 to 1. In 1930 there were 2, and in 1931 there were none at all.

Just as I finish writing this paper the *Medical Officer* of the 12th May reports that The diphtheria ward of the Alexandra Hospital at Montreal has been closed because there are not enough cases to warrant it being kept open. It was in 1928 that immunization against diphtheria was started in Montreal. The death rate that year was 28 per 100 000. In 1929 it fell to 15, in 1930 to 10, in 1931 to 6, and in 1933 to 2. Last year 52 063 Montreal children were immunized.

TUBERCULOSIS INSTITUTIONAL AND EDUCATIONAL ASPECTS

Objectives of the Campaign Against Tuberculosis

DR. KENDALL EMERSON, New York. With the founding of the Trudeau Sanatorium fifty years ago there was planted the seed of a sturdy tree, which has since spread its protecting branches over the lives of thousands of patients, at the same time removing from contact with their susceptible neighbors an equal number of foci each capable of indefinitely spreading the disease. With therapeutic aid in abeyance, with the initial step in handling any infectious disease, segregation, already under way, the first decade of the twentieth century offered the opportunity to gird our loins for a grapple with the leading cause of human mortality. Our resources were the medical profession and the public health service. Were these sufficient? Osler, Welch, Trudeau, Biggs, Bowditch, Billings, Janeway, Cushing, Musser and many other leading physicians of that period thought not, and it was they who added the National Tuberculosis Association to the attacking forces. Since then the nursing profession, social service and public education have all entered the ranks and the campaign has become proportionately complicated. From its inception, leadership has been and always will be in the hands of the medical profession. To the medical profession belongs the credit for recognizing and adopting the basis on which to found and build an effective campaign for the control of tuberculosis. Their objective was to secure the cooperation of the public in the project, and their method was through popular health education. It was agreed that the medical profession unaided had not the time or the training to assume the whole task, so it was decided to give birth to a volunteer health association, which should have both physicians and prominent laymen on its board of directors and which under adequate professional guidance should cooperate in getting across to the public the essential elements of health education. Two thirds of the board still consists of doctors, and there is good professional representation on the boards of all the affiliated and local associations, assuring essential medical direction.

The National Tuberculosis Association considers itself but one factor in the fight for the control of tuberculosis. It covets no position of dominance, its aim is to be a supporting educational arm of the public health service, working always under the skilled guidance of medical specialists. Under any other conditions it could feel no justification for its solicitation of funds from the public to enable it to make its due contribution to a properly coordinated general campaign against the disease. One of the first handicaps to the progress of the campaign was

found to be lack of adequate knowledge of the tubercle bacillus itself. Several discoveries of profound significance had already been made even at the beginning of the organized campaign. Among these was Theobald Smith's identification of the bovine type of bacillus, resulting in the salutary and effective attack on the disease at one of its sources, infected cattle. Here was an objective calling for immediate action and from the start purification of dairy herds, pasteurization of milk supplies and inspection of abattoirs have been aims relentlessly pursued by the campaign. Proof of the transmission of tuberculosis through direct contact with infected persons or with freshly deposited sputum led to antisputting campaigns and laws as well as to the abolition of the common drinking cup and towel and the inspection of food handlers and the regulation of restaurants and drinking places.

Clinically the early diagnosis of tuberculosis is of vital importance both for the sake of the patient's ultimate welfare and for the protection of the public against an occult spreader of the disease. Two priceless discoveries of those earlier days came to hand as aids to this most important task of the clinician: the tuberculin test and the roentgen examination of the chest. From the administrative point of view an essential in eradicating infectious disease is the accurate and complete reporting of cases.

The economic and social problems presented by tuberculosis are recognized not only as those pertaining to any infectious disease but also as those inherent in other chronic illness, entailing long disability, loss of earning power, expensive treatment and the suffering of dependents. These are definitely social problems in a field beyond the borders of strictly medical responsibility. The first effort to meet them systematically lay in the development of the public health nurse. Little by little the social worker has assumed an increasing share of this burden until now the care of a tuberculous patient, in the middle and less privileged classes of society, is clearly recognized as a dual problem, primarily medical but with an essential economic factor. One of the outstanding aspects of the campaign in recent years has been to draw into proper relationship these two phases of the tuberculosis problem as they affect the majority of cases individually and the whole community collectively. From the age of 6 to 16 the entire population of the United States is assembled in school. These years offer a priceless opportunity to put health education to work. It is an opportunity that has been sadly neglected up to very recent times, although for twenty years the sponsors of the campaign have been urging it and the Tuberculosis Association in particular has made large scale experiments to bring it about. In 1900 the death rate from tuberculosis was just over 200 per hundred thousand of the population, last year it was probably below 60 for the general public, and Dublin announces a rate just under 50 for the insured industrial group. Save in those epidemics yielding to specific measures of prevention, no similar achievement is on record in the history of human disease. How much the campaign has contributed, no one can say. It can scarcely be accused of holding up progress. Yet right here complacency meets a rebuff for, although the disease has been successfully demoted from first to seventh place as a cause of death, it still leads in the age group from 20 to 40, usually considered the prime of life. On the other hand a comforting example of what more may be accomplished by intensification of known methods is furnished in the Cattaraugus County demonstration, in which in seven years the rate has dropped from 70 to 38 per hundred thousand. Outstanding among objectives of the campaign is the relentless pursuit of medical and social research to shed light on the darkened areas in the field of epidemiology.

Within the limits of accepted knowledge the following procedures appear sound: protection of the milk supply, early discovery of cases, segregation of infectious cases, protection of the child against first infection or, if already sensitized, against reinfection, elimination of proved industrial hazards, more attention to age and racial groups that show the highest indexes of infection, promotion of acceptable standards of housing and nutrition, intensive research, and eternally hammering away at the task of teaching a none too receptive public how to take care of itself through health education. How is such

a program to be prosecuted? The answer points in just one direction toward the practicing physician. The outstanding objective of the campaign against tuberculosis in the immediate future is the enlistment in that campaign of greater professional interest. Practical control of the disease can be visualized by the more intensive use of even the imperfect methods that are already familiar. Slower progress may be expected as the fighting is turned at the more resistant areas. Skill, endurance and imagination are called for in dislodging the enemy from his more entrenched positions. These can be supplied by the practicing physician alone.

DISCUSSION

DR. HENRY C. SWANN, Chicago. There is only one objective in this work, *viz.*, to eradicate tuberculosis, but in accomplishing this end the problem becomes many sided. Of all the lapses, it seems that the greatest lies at the door of the medical profession itself. The physician must take more interest in what always will be his own work. It is regrettable that practitioners of medicine have not kept abreast with the newer knowledge of tuberculosis. For the cause of this one does not have to look far. First, tuberculosis was for a long time considered a hopeless disease. Second it was a long drawn out process when not fatal. Third, the chronicity of the disease did not permit of as sudden or striking results as could be obtained with acute diseases. The result was that the tuberculosis field was almost completely deserted by physicians. Fortunately for the tuberculosis problem a few doctors contracted the disease in those early days, else we should still be leaving the care of the tuberculous to laymen and nurses. From Trudeau down to recent times the bulk of tuberculosis men have been those who had contracted the disease and were forced into the work. There is no excuse for such conditions to prevail today. The disease may now be treated as actively as any other disease. To the indispensable hygienic treatment there have been added the newer methods of diagnosis and newer forms of surgical treatment. Practitioners represent the greatest possible potential factor in early case finding, but much of their opportunities are wasted because of lack of knowledge of the disease. The most important problem, therefore, resolves itself into an educational campaign on behalf of this group. More attention should be given to curriculums in medical schools. Postgraduate work in tuberculosis should be given. Students should be taught the characteristics of early infection its pathology in primary and postprimary types its clinical course its interesting roentgenologic aspects and the immunity and allergic reactions. Many times early lesions are missed on physical examination. It is of the greatest importance to teach that the early lesion is predominantly of a benign character. It does not always produce clinical symptoms nor are the physical manifestations constant. So many times in the past these early cases have been missed by the physician, that his confidence has been shaken in his ability. With this foundation, the frank clinical disease will have more meaning, the doctor will regain his place in the tuberculosis campaign, and the greatest need will be supplied.

The Undergraduate Teaching of Tuberculosis

DR. JAMES ALEXANDER MILLER, New York. I approach the question of the undergraduate teaching of tuberculosis to medical students as a part of the course in internal medicine and to a lesser degree also in surgery, rather than from the point of view of a specialty in medicine.

The idea that tuberculosis is a systemic infection, which develops clinical manifestations in practically all organs of the body should constantly be borne in mind. At graduation the usual medical student has an inadequate appreciation of the problems of tuberculosis, and his preparation for the diagnosis and treatment of the disease is far from satisfactory. Students first come in contact with cases of pulmonary tuberculosis through clinical material employed for the teaching of physical diagnosis, an approach which appears to give them a lasting impression that the physical signs are of predominant importance in the recognition of the disease. As a matter of fact, the physical signs in such cases are usually those of lesions already far advanced. It is now being generally recognized as Brauning has put it, that early pulmonary tuberculosis must

be seen, not heard. This means that a much greater emphasis than at present should be placed on the study of roentgenograms of the chest. It would appear desirable from the first contact of the student in his second year with pulmonary tuberculosis that in connection with the teaching of physical diagnosis there should be emphasized its correlation with the corresponding pathologic conditions at autopsy and the study of the pathologic changes during life, which is afforded by the roentgenogram.

The close personal relationship established between physician and patient is the best sort of training for the development of that broad understanding which we like to think of as one of the most admirable qualities of our profession. Nowhere can this be developed so well as in the management of chronic disease such as tuberculosis, demanding as it does a full knowledge of all the personal, social and economic factors involved, as well as a close scrutiny of many symptoms, which are often slight and which require painstaking study to appreciate their significance. To place before the student the necessary clinical material in a proper way, a special chest service and a properly trained staff are essential. This service should be closely integrated with that of internal medicine, not alone should the members of the staff be specialists in chest diseases but they should also have a broad fundamental experience in general medicine.

Because the study of pulmonary tuberculosis affords the opportunity for special training in chronic diseases of the lungs that are not tuberculous, I would emphasize the importance of a general chest service for chronic pulmonary disease, including pulmonary emphysema and fibrosis, bronchiectasis, pulmonary abscess, pneumoconiosis and malignant diseases of the lung. If to this material are added the numerous incidental medical and surgical complications that occur in the course of tuberculosis and the incidental complicating general diseases that occur in any such service, we have offered to us a wide variety in the teaching material available for students, which, if properly studied and properly taught, deserves to have such a service rank in importance with the regular general medical service in the assignment of teaching hours for the undergraduate student. If there is added to this the opportunity for a few days of intensive study in a neighboring sanatorium to learn the details of the sanatorium methods of treatment and the wide variety in the course of the disease, a very satisfactory teaching setup for bed cases becomes available. In addition, there is an immense clinical material available for the study of ambulatory cases in the outpatient department. Here, too, the special tuberculosis clinic should include the other chronic chest diseases and it is here that the opportunity for the teaching of early diagnosis is afforded and the follow-up after-care so important in the management of any chronic disease, particularly tuberculosis. But even more important than this, the outpatient department affords the opportunity for application of the modern principles of preventive medicine, and this is linked closely with the social problems of medicine.

The organized efforts for the prevention of tuberculosis through public health agencies as well as numerous coordinated private agencies, and the methods of health surveys as a foundation for preventive health examination are too little known by the medical student and consequently by the younger practitioner. The underlying principles involved can be taught to the student systematically in the tuberculosis clinic. Some efforts along these lines are already being made in some medical schools, but they are still inadequate. Properly developed this combined medical, public health and social approach to the problem would lead to a broadening of the whole basis of the understanding of the students of the social background, so important in many diseases, and the many home and economic elements involved, and also would impress on them their responsibility for an understanding of the methods of spread of the disease and consequently their responsibility for its prevention as well as for its treatment. Through the social service department each student should have an opportunity to visit and study on the ground the homes and working places of a few patients under their care and to study the public health aspects of the problem as developed by examination of contacts, particularly children, the importance of untoward environment and the possibilities of its remedy.

Another important aspect of the problem is the psychologic one. Any patient with chronic disease faces a great psychologic and emotional problem as well as a physical one.

Of course, the study of the pathologic conditions involved is essential. The treatment of pulmonary tuberculosis has been revolutionized by modern collapse methods, beginning with artificial pneumothorax and going on to include the various more radical surgical procedures. The principles of modern thoracic surgery are largely based on experiences in pulmonary tuberculosis and similar chronic infections. It has developed on a sound basis only if there is a close cooperation between the surgeon and the internist. Therefore a chest service should have its closely correlated surgical unit and the student should have an opportunity to study the course and treatment as a whole under the combined guidance of both the internist and the surgeon. In general, we should begin the second and third year of the medical students' life with a somewhat different approach to chest diseases, emphasizing of course physical diagnosis but also enabling them to understand the limitations of this one method of procedure. Also during this phase of training it would seem logical to begin to include x-ray and pathologic material, and all through the entire course much more training in the interpretation of roentgenograms should be afforded than now exists in most medical schools. The time is gone by when the practitioner in medicine would be satisfied to accept the report of the roentgenologist as giving him a full interpretation of the knowledge to be obtained by this important method of examination. It is in the fourth year during the period of so called medical clerkship that most of this teaching material on chest diseases should be placed before the undergraduate student. Each student should certainly at least have one month, and preferably six weeks of continuous all-day study, with a schedule including the various angles of approach. The Bellevue Hospital Service comprises 180 beds, mainly for tuberculosis, but between 15 and 20 per cent of all patients are suffering from chronic nontuberculous chest conditions. There are over 3,000 admissions each year. Many of the basic requirements that I have outlined as desirable for teaching tuberculosis to undergraduates have been provided at Bellevue. We feel that we need a little more time for each student and that six weeks would be none too long for each fourth-year student to spend in our service. In general, the aim of our teaching is to provide first the material. This consists on the one hand of the patients specially selected because of their type of ailment, and on the other hand of the student, the material of which the physician is to be made. With this human material we provide the tools and the technic for the training of the student under expert guidance. He is also encouraged to learn to think for himself and thus to acquire wisdom rather than to accumulate knowledge. Having arrived at this point he may be a very well trained man, but he is not yet a physician. That end is achieved only if and when the trained man with all his technic turns to the consideration of the original material that is, the human individual under his care. When the proper contact between the individual patient and the individual student occurs, then is created the spark which transforms the technically trained student into that rare product, the true physician. If, under the inspiration of proper leadership, this personal human interest can be widened to include the community environment surrounding the individual patient one may expect to obtain that still rarer flower of medical education, the trained physician with social vision and broad human understanding.

DISCUSSION

DR JAMES J. WARING, Denver: While I am in accord with Dr. Miller in recognizing the superiority of the x-rays to the stethoscope in the detection of minimal tuberculosis of the lungs, I would urge great care not to depreciate the art of painstaking physical examination. For the inexperienced student and the careless hurried doctor, the tendency is still, after the lapse of more than a century since its discovery to reach for the stethoscope at the beginning of a physical examination rather than at the end. Care must be taken lest reliance on the x-rays lead to neglect of the development to the highest point of efficiency of inspection, palpation, percussion and auscultation. Tuberculosis must be studied throughout its entire

course. Serial roentgenograms enable one to review, in a few moments, the long drawn out evolution of pulmonary tuberculosis. They are most instructive when they encompass months and even years and when carefully related to conduct and to incidental events of the patient's life. One's morbid existence is caught on the film and may be preserved indefinitely for leisurely study and instruction. Since infection, reinfection or complications may arise today or tomorrow, films should be preserved at least until the death of the patient. I am pleased that Dr. Miller dwelt on the emotional or psychic problems of the consumptive, because it gives me opportunity to speak of the work of the Psychiatric Liaison Department at the University of Colorado School of Medicine and Hospitals. This project, conceived by Dr. Franklin Ebaugh and supported by the Rockefeller Foundation, has been in operation only a few months under the capable direction of Dr. Edward G. Billings. It aims first to effect a more intimate relationship between the personnels of the Colorado General Hospital and the adjacent Psychopathic Hospital and, secondly, to establish psychobiology and psychiatry as efficiently functioning services in the out-patient medical and surgical clinics and the medical and surgical wards of the General Hospital. Through lectures, clinics, ward rounds, seminars, conferences and informal discussions with students and staff, it is hoped to develop a common sense psychiatric approach for the betterment of the patient's condition. The student is being taught in a very practical fashion the technic of discovery and relief of mental and personality disorders. Each day testifies to the success of the plan. In any brief consideration of the teaching of tuberculosis, one can only acknowledge the accuracy of Dr. Miller's premises and wish that every medical school could have a duplicate of the setup at Bellevue.

DR. J. N. BAKER, Montgomery, Ala.: This subject makes a strong appeal to those who are deeply interested in medical licensure. Medical schools are learning that the practice of scientific medicine today is about three fourths preventive and one-fourth curative, and when they incorporate those principles into their daily teaching they are turning out practitioners on whom great reliance can be placed. It is gratifying to see the training they are now given as contrasted with the training of the practitioner who has been in active work for twelve or more years. One of the big problems in the control of tuberculosis is an extension of our educational methods down to the practicing physician of today. If the curriculum might somehow be permitted to seep down into the practicing physician of today, it would be an immense help to those who are trying to exercise control in the communicable diseases. If physicians can be made to realize not only that cure depends on early diagnosis but that their financial interests are materially enhanced through an early recognition and the proper application of modern surgical therapy to the treatment of that, some sort of dent will have been made in the problem.

DR. CHARLES J. HATFIELD, Philadelphia: At the University of Pennsylvania we endeavor to have the teaching of tuberculosis an integral part of the teaching of general medicine. It is the general practitioner who is going to come up against almost 100 per cent of the cases. All through our teaching we try to emphasize the preventive side, both on the personal family lines and also on the epidemiologic lines, the community health. In the second year in Philadelphia in the teaching of physical diagnosis, we have the use of tuberculous patients as contrasted with the normal chest. There is also fifteen hours devoted to the pathology of tuberculosis, lectures and laboratory work. Only five hours is assigned to the bacteriology of tuberculosis. In the third year, lectures on tuberculosis are included in the program of lectures on general medicine. But at the Phipps Institute we have tried to give an intensive survey of the whole field of tuberculosis. We allow only sixteen hours for this particular survey but in that there are given to groups of sixteen four short lectures of only thirty minutes each. Then these groups of sixteen are split into groups of four, and those four are instructed for six hours four different sessions, in the actual handling of tuberculous cases starting with the history taking, physical examination, differential diagnosis, treatment

and prophylaxis. Then to groups of eight a careful outline of roentgenologic work is given. To groups of eight, again, there is an hour assigned for the discussion of the laboratory procedures useful in diagnosis and prognosis. To groups of sixteen two different sessions are devoted to instruction in treatment medical and surgical, and, again, to groups of eight there are two sessions devoted to a demonstration of surgical treatment and its results, including fluoroscopic examinations of patients and demonstrations of the technique of artificial pneumothorax. To groups of sixteen a session is devoted to the presentation of pulmonary tuberculosis as a public health problem. Throughout the program emphasis is laid on the preventive side of tuberculosis from the standpoint of the patient, his family and the community. In the fourth year from eight to ten hours is devoted to bedside instruction in the tuberculosis department of the Philadelphia General Hospital. Students of the Graduate School of Medicine of the University of Pennsylvania are given a sixteen-hour course at the Henry Phipps Institute. The plan is similar to the course for third year students with however greater emphasis on physical examination and treatment. At least one clinical demonstration of phlebotomy, pneumolysis and pneumothorax is provided.

DR R. E. PINKERTT, ALBANY, N. Y. In Albany we have had the opportunity of watching the effects of Dr. Miller's program of medical education by virtue of our observations of physicians who have established themselves in the various parts of New York State. There isn't any question that Dr. Miller conveys to every medical student that the tubercle bacillus is the alpha of the clinical phases of tuberculosis and the omega of the public health features of that disease. If that is kept in mind naturally, physicians not only will be tuberculosis conscious from the standpoint of the geographic distribution of pathologic conditions within the chest but also will at least look for its manifestations in the sociological and economic phases. In 1919 the state department of health of New York came to the conclusion that if further progress was to be made in tuberculosis control, the physicians in the various parts of the state should be taken into the picture and that a place for the physician, a place for the public health official and a place for the sanatorium should be well defined. A consultation type of clinic was inaugurated which since that time has been conducted in approximately thirty or forty counties throughout the state. No patients are accepted at those clinics unless they have an admission card from their family physician or if they cannot afford a family physician they may secure an admission card from the health officer of the community in which they reside. We have had 100 per cent cooperation on the part of the practicing physicians, and they think of tuberculosis not alone as a clinical entity but also from its public health significance. As a result of this development of good will we have established an esprit de corps with the physicians which, I think correctly, has been paying benefits to the patients. The benefits accruing to the community cannot be measured in dollars. As a result of that service for the last two years, of the cases which we have diagnosed as positive, one of every seven people who come into our clinics have clinical pulmonary tuberculosis and one out of seventeen that are examined at these clinics is discovered as a new case of pulmonary tuberculosis. We have about 1,200 physicians participating in this service. Fifty-five per cent of our patients come to us giving a history of known contact with the disease. Among the females examined who gave a history of contact and who have been followed up, 58 per cent are in the minimal stage of the disease as against 44 per cent of the male cases. Of the noncontact groups there are 36 per cent of the females who are in the minimal stage, and 25 per cent of the males. In other words, over half of the cases that come to our clinic are in the minimal stage of the disease. The incidence in these groups is another interesting manifestation of the peculiarities of tuberculosis in contacts. In the females who know of no contact with the positive case the peak of incidence is found between the ages of 25 and 35, whereas in the males who know of no intimate contact the peak of incidence is between 35 and 45. I want to compliment Dr. Miller because of the work he is doing in educating doctors in New York.

Some Historical Aspects of Tuberculosis

DR LEWIS J. MOORMAN, Oklahoma City. Tuberculosis may have been the first born of the mother of pestilence and disease. Laminated skeletons of prehistoric periods bear the marks of tuberculosis. The Code of Hammurabi, written more than 2,000 years B. C., indicates a possible knowledge of tuberculosis. Aretaeus, in the first century A. D., gave accurate clinical descriptions of tuberculosis and suggested routine treatment similar to that employed today. Galen preserved the teachings of Hippocrates and recorded his own observations. He was one of the first to employ climate in the treatment of tuberculosis recommending the balmy zones immediately surrounding Vesuvius. The period of the dark ages was characterized by twelve centuries of lethargy resulting from a combination of religious prejudices against the opening of the dead human body and a static condition of existing knowledge due to galenic fixation. The works of Aristotle, Hippocrates and Galen furnished the foundation for the renaissance of medicine in the fifteenth century, but no progress occurred until Sylvius in the seventeenth century gathered up the lost threads and added his work on the pathology of tuberculosis.

Not until 1761 a hundred years after Sylvius can another genuine advance be recorded. Then came Auenbrugger "knocking at the human thorax." Fifty years later Laënnec put the cruse of diagnosis forward with unprecedented rapidity. Laënnec's revival and amplification of auscultation and his invention of the stethoscope enabled Corvisart to check the results of percussion in the living body, whereas Auenbrugger may have failed to establish the value of his method because he could confirm his observations only at autopsy. Laënnec, more truly than any one who had gone before, brought together the varied clinical and pathologic manifestations of tuberculosis and proclaimed the unity of phthisis. The great teacher Louis, who established clinical medicine throughout the world correlated in a scientific way the symptoms elicited at the bedside with the pathologic changes found at autopsy and inaugurated valuable statistical methods of recording his observations. Virchow, advancing from Bichat's tissue pathology to cellular pathology, made valuable contributions to the knowledge of tuberculosis. However he joined the dualist Schoenlein, who coined the word tuberculosis in order, as he thought, to differentiate the nodular tubercles from the cheesy patch characterizing phthisis. Thus is seen the perspicacity of Laënnec with reference to the "unity of phthisis" blocked by the unfortunate and misguided application of a scientific advance. Not until the discovery of the tubercle bacillus were the dualists routed and the unity of tuberculosis finally established. Villemin, Boudignon, Beddoes, Brehmer, Dettweiler, Forlanini, Trudeau, Robert Koch and many others then made outstanding contributions.

As one studies the course of this malady, one is confronted with a strange paradox. The tubercle bacillus resident in the human organism gives rise to two distinct manifestations: the depletion of physical energy and the stimulation of mental activity. In those who are endowed with exceptional mental qualities and are at the same time suffering from tuberculosis often there seems to be a strange psychic stimulus bent on creative accomplishment. In some individuals only the vision of death brings a consciousness of "the divine reality of life." It seems reasonable to say that the progress of medicine has been largely dependent on the stimulus of this dual influence. No doubt Galen periodically came under the spell of tuberculosis. He reports having had two physical breakdowns before he was twenty.

Franciscus Sylvius (1614-1672), who it is thought suffered from tuberculosis not only stressed the importance of anatomic tubercle in the lungs but pointed the way for all great clinical teachers.

William Withering (1741-1799), reported as having died of tuberculosis, gave to the world "An Account of the Foxglove and Some of Its Medical Uses." What a godsend to fibrillators! He also advocated a therapeutic regimen approaching the modern treatment of tuberculosis.

Maximilian Stoll (1742-1787), who succumbed to tuberculosis sharply defined its clinical manifestations. No doubt the consciousness of its presence in his own body had much to do

with his untiring interest. He succeeded de Haen at the University of Vienna, where he directed the clinic in the general hospital, exerting a wide influence in the field of clinical investigation. Corvisart translated Stoll's aphorisms ten years after the author's death. It was here he first learned of percussion. Had it not been for Stoll's influence percussion might have remained dormant and untaught in the poor French translation that antedated that of Corvisart by more than a quarter of a century.

Benjamin Rush (1745-1813), according to Jacobson, was a victim of chronic tuberculosis. He was one of the first to give tuberculosis a place in the annals of American medicine.

Bichat (1771-1802), who died of tuberculosis at the age of 31, made a great contribution to pathology in that he progressed from Morgagni's organ pathology to tissue pathology within the organ.

Laennec (1781-1826) died of tuberculosis at the age of 45. His reaction to his environment was much like that of St. Francis, Voltaire, Robert Louis Stevenson, Keats, Shelley and Sidney Lanier. With remarkable industry and conspicuous discrimination, "he drew up a minute history of nearly four hundred cases of disease" before he was 22 years of age. These carefully tabulated case histories served as a foundation for his future researches and discoveries. When Laennec came upon the scene, the diagnosis of diseases of the lungs and heart was more difficult than that of any other internal organ. In a short time he had made the most difficult diagnostic tasks relatively easy. In half the time now allotted for a medical education, Laennec, virtually without chart or compass, "observed, recorded, tabulated and communicated" practically all that is now taught with reference to the diagnosis of diseases of the thorax.

Louis (1787-1872), who was one of the world's greatest clinical teachers, also suffered from tuberculosis. When 34 years of age he gave up private practice to pursue his clinical and pathologic investigations, the results of which were reported in a volume of 600 pages known as "Louis's Researches on Phthisis." It is impossible to estimate the value of Louis's contribution to medical education. His spirit inhabits the wards of every well ordered hospital, his influence is evident wherever the principles of clinical medicine are taught.

DISCUSSION

DR. KENNON DUNHAM, Cincinnati. Dr. Moorman did not touch on the Biblical references to tuberculosis. The Egyptians before the Jews left Egypt had developed a great deal of medical knowledge, locked up in Deuteronomy and Leviticus. Moses wrote "Those who are stricken with cough after illness." It was known long before that. Along in 1700 the Mohammedans the Arabians, were doing the best medical work, and they discovered tuberculosis in cattle. Therefore it became a fetish to have anything to do with eating cattle. The infectiousness of tuberculosis was also recognized a long while ago. Then there are two fundamental pieces of work which I think bear well on our work of the present day and which are not generally recognized. Birch Hirschfeld is the man who gave us the most perfect outline of the bronchial tree. In 1898 he showed that not in the apex but in the posterior part of the upper lobe was the place where one should look for the earliest finding of pulmonary tuberculosis. He wrote so clearly and so accurately that this was called the posterior apical bronchus of Birch Hirschfeld. Today a great deal is being said about the subapical tuberculosis in contrast to the apical lesions, also about subclavicular tuberculosis. That is an x-ray mistake. That is not below the clavicle but it is below the apex in the posterior part of the upper lobe and Birch Hirschfeld is the man who should have the credit for that. In giving history to medical students it is worth while to teach them the importance of the accuracy of the man who found certain things. William Snow Miller is the man working with Mall at Clark University who worked out the anatomic unit of the lung which is absolutely essential to the understanding of pulmonary tuberculosis especially so far as it refers to exudate. The biggest thing is to teach the student how to translate x-ray densities into pulmonary pathologic changes but especially, above everything else, into pulmonary anatomy.

Dr. Hatfield has spoken about what they do in teaching tuberculosis in Philadelphia. We try in Cincinnati to make the student understand the five properties of sound as they vary over the normal chest. A class of four are put together, and they have to learn how the different breath sounds and percussion notes vary over those four normal chests, and then they are allowed to listen to a chest of tuberculosis. These are men after they have had their course in physical diagnosis. Then they are shown how the diseased chest differs from that. The big point is that in auscultation the breath sounds vary in various parts of the normal chest and over different chests that are perfectly well. In addition to that, disease varies greatly. When teaching tuberculosis, one should keep the fundamentals before one's students. First of all, they must learn the normal and compare that with the pathologic. That applies to the roentgenogram.

Function of the General Hospital in the Treatment of Tuberculosis

DR. J. ARTHUR MYERS, Minneapolis. The use of the general hospital for the care of tuberculous patients is not a new idea. Centuries ago, in Italy and Spain, these patients were freely admitted to such institutions. Bodington of England conceived the idea of congregating tuberculous patients in an independent institution. The hospital that he used for this purpose failed not only because of the lack of support of the medical profession and the public but also because of the active opposition which developed against his views. In 1858 Brehmer, with views somewhat similar to those of Bodington, established a special institution for the tuberculous in Germany. One of his medical assistants, Dettweiler, developed two similar institutions in that nation. After reading of the work of Brehmer and Dettweiler, Trudeau established the Adirondack Cottage Sanitarium at Saranac Lake, N. Y., in 1885. Although the Channing Home in Boston was in operation for the isolation and palliative care of consumptives as early as 1857, Trudeau's institution was the first in this country actually to offer any hope of recovery for the person who had clinical tuberculosis.

Since the time of Trudeau's initial step in this country, approximately 700 sanatoriums for the tuberculous have been constructed, and the actual bed capacity in these institutions now closely approximates 80,000. The work done by the physicians of these institutions will go down in medical history as one of the greatest accomplishments of the profession. The sanatorium contributed what has proved to be its greatest service, namely, the isolation of the patient. In the beginning of sanatorium work, to protect the entire nation against exposure through isolation of open cases must have seemed hopeless, because of the large number of sufferers from this disease. Today no one would doubt that taking about 80,000 persons with open tuberculosis out of their communities is having a very marked effect on present morbidity and mortality and will have a greater effect in the next generation. This work, together with that of private practitioners of medicine and the veterinarian's unequalled demonstration of tuberculosis control, has brought about an entirely different situation with regard to the tuberculosis problem than existed even one or two decades ago. As early as 1916 the National Tuberculosis Association went on record as recommending the use of general hospitals for tuberculosis. This action was reaffirmed in 1921 and again in 1924. In 1920 the surgeon general of the United States requested action by the American Medical Association concerning the admission of tuberculous patients to general hospitals and in 1921 the House of Delegates endorsed a recommendation to the effect that general hospitals be used in this capacity. Thus, the two most instrumental organizations in tuberculosis control have recommended that general hospitals be utilized in the program. Already a good many general hospitals have opened their doors to tuberculous patients. Moreover, there has been a recent awakening of the members of the medical profession to their responsibilities, the possibilities of marked achievement, the ease with which the disease is diagnosed, and the success with which it may be treated, that may be likened to the renaissance in general medi-

cine of a few centuries ago. This increased interest on the part of the general medical profession, together with the past accomplishments, has brought about a situation so different from that of the past and an outlook so hopeful that it can now be truthfully said that we have entered on a new era in the field of tuberculosis. The goal is to have diagnostic and therapeutic centers established in the offices of at least 100,000 physicians throughout the country, with the hospitals on whose staffs they hold membership offering adequate facilities for their patients who need hospital care.

Whenever a general hospital decides to set aside space for tuberculous patients, some objections are registered. If it is a private institution patients and their families object to paying for the services rendered by the hospital and its staff. This is because of the fact that many of the sanatoriums are tax-supported institutions which were originally intended for the care of the poor but which have in more recent years accepted patients regardless of the financial status on a part pay basis.

Another objection often voiced is that the general hospital is not capable of rendering as good service as the sanatorium. Obviously, the service will depend on the management of the institution. If service is poor in a general hospital there is no reason why it should not be improved through change of management. There is nothing mystifying about the diagnosis or treatment of tuberculosis. The general treatment of tuberculosis consists of conservation of energy, adequate diet and good atmospheric conditions. Strict or partial bed rest as required may be had in any good general hospital, and dietary needs can be provided. The open air treatment of tuberculosis is being rapidly abandoned. Any well ventilated room is adequate. Conditioned air is ideal, and there is little doubt that plants providing such air will be installed in large numbers of general hospitals during the next few years.

Collapse therapy is the most important special measure employed in the treatment of pulmonary tuberculosis. The most effective and most extensively used method of collapsing the lung is artificial pneumothorax. Artificial pneumothorax has long been carried out in the home and in the general hospital with satisfactory results. Surgery of the phrenic nerve, such as phrenicoplasty and phrenic excision is very valuable in properly selected cases. The nerve is easily accessible and any careful surgeon can quickly learn the necessary technique. When other methods of collapse therapy fail extrapleural thoracoplasty is often indicated. There should be on every general hospital staff, and is on many of them, one or more surgeons especially interested in chest surgery, who if not already trained, can soon become proficient in extrapleural thoracoplasties. Extrapulmonary tuberculosis often requires surgical treatment, such as that involving the bones, joints and kidneys. The tuberculous patient is not immune to diabetes, appendicitis, cholecystitis and pelvic disturbances. On the general hospital staff there are always members available who are especially interested in such conditions and by reason of training and experience are capable of providing the best treatment. Therefore the needs of the tuberculous patient can be adequately met by the general hospital. Indeed, some of the larger sanatoriums have been converted into general hospitals through the establishment of obstetric, pediatric, surgical, and nose and throat services, and other departments found in a general hospital.

Another objection to the general hospital admitting tuberculous patients is on the basis of contagion. There is no reason why contagion should be feared. The technique employed in any good contagious disease service is adequate, anything less than this introduces an element of danger. Unfortunately, in many cities only one or two general hospitals, and these usually are tax supported institutions, provide contagious disease services. The result is that the private general hospitals lose all the work in this field, and the physician who diagnoses the case frequently loses it because he is not on the staff of the particular hospital providing such service. A contagious disease service added to every good sized private general hospital could be made to increase the revenue of the institution and, better than this, would make it possible for the hospital to render a much better service to the citizens of the community than it is now doing. The danger of contagion with reference to students of nursing and medicine in general hospitals, as well as sanatoriums, has received some emphasis but needs much more. In

the Minnesota General Hospital for a number of years tuberculous patients have been admitted for chest surgery and similar procedures to the contagious disease service. Here it has not been unusual to have a patient with measles in one room, one with tuberculosis in the next, with diphtheria in the next, and so on. So far we have not seen a single case of cross-infection nor have we seen a nurse in this service fall ill from tuberculosis. During the past year we sent a questionnaire to all the students who had graduated from the University of Minnesota School of Medicine since 1920. Much to our surprise, among the physicians who graduated in the earlier years of this period only approximately 5 per cent have had tuberculin tests or x-ray film examination of their own chests, whereas, of those who had graduated in the last two or three years, about 97 per cent had been so examined.

It is a well established fact that, when symptoms of pulmonary tuberculosis appear from 80 to 85 per cent of the patients have moderately to far advanced disease, also, most tuberculous patients do not present themselves to physicians for examination before symptoms appear. Moreover, chronic pulmonary tuberculosis usually exists over two or more years before causing any outward manifestations of its presence. If the physician has detected their disease before it has broken down, such patients do not need to be admitted to a contagious disease service and, if he treats it adequately, the majority of such patients will never spread tubercle bacilli from that particular lesion. Patients with positive sputum should always be admitted to the contagious disease service. Many of them through collapse therapy will have their lesions brought under control so that their disease is no longer communicable to others. When this time arrives, they do not need contagious disease technique any more than the patient who has recovered from typhoid or diphtheria. However, in each of the three diseases one must constantly keep in mind the possibility of the carrier. The 80,000 beds now available in our sanatoriums are inadequate to solve the problem as quickly as it should be solved. There is no thought of displacing any sanatorium when the number of patients is adequate to keep it filled to capacity, it is only a matter of supplementing the very fine work now being done by these institutions.

Because the mortality and morbidity, as well as the number of potential cases of clinical tuberculosis, is rapidly decreasing, it would seem poor economy to provide for more sanatorium beds except in a few places where sanatoriums have been lacking. It would seem far wiser to use beds in general hospitals, of which there are vacant at this time approximately 150,000. Patients who can afford to pay for services should do so and those who cannot should have the fees of the hospitals paid from tax funds, as is done in the case of sanatoriums. It is far better economy for a political division to pay for its patients in general hospitals on a cost-plus basis than to erect new institutions. If the program of tuberculosis control continues to succeed, the demand for sanatorium and hospital beds will decrease rather rapidly, indeed, many now living should see the time when numerous sanatoriums and tuberculosis divisions in general hospitals will be closed for lack of patients. In fact in one state the sanatorium capacity, which was frequently inadequate in the past, has now by reason of decrease in morbidity become greater than the demand. If in addition all physicians and general hospitals attack the problem, a tuberculosis situation can be created for the people of this country as good as that which has been created for cattle.

DISCUSSION

DR. EDWARD S. MCSWEENEY, New York. Up to recently there was a general acceptance of certain fundamental principles of treatment of tuberculosis. Discussion during the last few years of newer methods seems to have created the impression that these principles have been abandoned by tuberculosis men and a whole new scheme of treatment adopted. So far as I know, nothing of the kind has taken place. Additions have been made to what we previously had but what we previously had has lost none of its own values and is still held precious. I am here as president of the American Sanatorium Association, and that is the brief I hold, but I shall try to give a fair presentation of the different sides of the matter. Bodington and Brehmer evidently thought of tuberculosis as some sort

of nutritional disorder. They had observed that patients who quite fortuitously rested in the open air and gave particular attention to their nutrition improved and of the few who stuck to it for a long time many apparently recovered. Out of these considerations, medical and personal, grew the concept of the sanatorium—a place located, built, equipped, staffed and managed for this particular purpose. If patients not very sick in the ordinary use of the terms must spend weeks or months in idleness in bed or on reclining chairs, freedom from the sense of confinement means much. So sanatoriums have open porches and angulated arrangements to insure breadth of outlook and a sense of freedom, lawns and flowers, woods, the open sky day and night and all the factors that go to make for contentment over a long period of residence. Contrast this with the hospital, which may be located in the midst of a busy town, having nothing but closed rooms and wards. Brehmer's concept of a sanatorium remains valid. The problem narrows itself to a consideration of what has since been developed, which should modify our handling of it. Since 1858 there have been only two developments applicable to the treatment of tuberculosis of really first rate importance, namely, x-rays and the comparatively recent wide use of pneumothorax. More routine and research lung work with x-rays has been done in sanatoriums than in all other places combined. The x-rays offer no argument for or against sanatoriums or hospitals. Pneumothorax demands more consideration. Any one who does not recognize its value simply doesn't know enough about it. Its field has already been widened and one hopes will be still further developed. As an adjuvant and improvement to sanatorium treatment there is no question about it. Unfortunately, not all cases for one reason or another can be given it nor in many can it be successfully maintained. The process too is not free of danger even to life although this is small but it is frequently accompanied by disabling effusions and all too frequently by empyema. As I said of the x-rays, the same is true of pneumothorax—more routine and experimental use has been made of it in sanatoriums than in all other places combined. Taking all these facts into consideration, I do not see how considered judgment of the values involved can arrive at any other conclusion than that the sanatorium with judicious use of these newer weapons remains the place *par excellence* to treat tuberculosis and that there is no sufficient reason to transfer the treatment of such cases when avoidable to hospitals, especially urban hospitals. Until sanatoriums were developed no method of curing tuberculosis had been evolved although man had been familiar with the disease since the time of the Pharaohs and they have a seventy-five year record of substantial achievement for their patients and the public. No such therapeutic system should be lightly discarded. What may be said on the positive side for general hospital treatment? I have answered this question in one aspect. That which remains is consideration of service to tuberculosis cases which must be treated out of sanatoriums and in this I see no reason why general hospitals should not participate as Dr. Myers has so well discussed to their own and their patients' advantage. There are diagnostic problems best solved by hospital study, and in some places a hospital may serve a useful purpose as a collecting and distributing station. The best solution of a local problem may be a tuberculosis hospital or a tuberculosis wing or a tuberculosis ward, but I want to add my plea to Dr. Myers that the general hospitals not too lightly dismiss consideration of their obligations and opportunities in this respect. The main consideration is that whatever service is set up it be manned by interested physicians and not be a mere adjunct to some general medical scheme. I have made an omission which was intentional. I refer to surgery, more especially rib resections. Such an operation, if successful, is a supreme procedure to the patient, but I am afraid that tuberculosis offers no field for the mechanical doll concept of the treatment of human ailments so prevalent among surgeons. Such work as I have referred to is a specialty within a specialty, and good results can be hoped for only at the hands of operators experienced as well as deeply interested in the problem, and naturally deft technicians with well trained operating teams and carefully applied preoperative and postoperative technique.

(To be continued)

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

April 18 Catarrh
April 25 May Day or All Year Round?
May 2 Being Your Age (4:30 p. m. Chicago daylight saving time,
3:30 p. m. central standard time)

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

April 16 Meeting a Challenge W. W. Bauer, M.D.
April 23 Sudden Death Morris Fishbein, M.D.
April 30 Child Health W. W. Bauer, M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Personal—Dr. William B. Wells, Riverside, has retired as health officer of the city and of Riverside County on account of ill health. He has been succeeded by Dr. Wendell A. Jones, Riverside.—Dr. Esther Rosencrantz, associate professor of medicine, University of California Medical School, San Francisco, has been appointed medical adviser to the San Luis Obispo Tuberculosis Sanatorium.

Bills Passed—The following bills have passed the senate: S. 21, proposing to regulate the production and distribution of serums, vaccines, bacterial cultures and viruses, and to require the licensing by the department of public health of persons manufacturing, preparing and distributing such products, and S. 468, proposing to amend the medical practice act so as to authorize courts on the application of the state board of medical examiners to enjoin the unlicensed practice of medicine.

Southern California Meeting—The Southern California Medical Association will meet at the Arrowhead Springs Hotel, May 3-4. Among the physicians on the program will be:

Harold M. Walton, Loma Linda, Blood Picture in Hodgkin's Disease and Polymyositis with Special Reference to Eosinophilia
George Franklin Farnham, Los Angeles, Treatment of Gonorrhea
Harris Garcelon, Arrowhead Springs, Mucous Colitis
Adelbert M. Moody, San Francisco, Endometriosis of the Appendix
Cysticercus Cellulosa
Percival A. Gray, Jr., Santa Barbara, Hypoglycemic Headache
Albert H. Elliott, Jr., Santa Barbara, Studies in Peripheral Vascular Disease
Walter F. Pritchard, San Bernardino, Intravenous Urograms
Albert D. Neubert, Redlands, Spinal Anesthesia
Mark A. Glaser and Herman M. Beerman, Los Angeles, Depressed Skull Fractures, Clinical and Experimental Study
John C. Jones, Los Angeles, Surgical Treatment of Chronic Empyema
Joseph A. Pollak, Los Angeles, Malignancy of the Heart
Harry H. Wilson, Los Angeles, Management of Alcoholism

COLORADO

Personal—Dr. Roy L. Cleere, Denver, has been named a member of the state board of health, succeeding Dr. Samuel R. McKelvey, Denver, who had served on the board since 1911.

Bill Enacted—S. 277 was approved by the governor, April 1, making it unlawful for any person to receive hospital care with intent to defraud the hospital of the amount due it for such service and also making it prima facie evidence of intent to defraud for a patient to leave a hospital without paying his bill.

Bill Introduced—S. 581, to amend the laws relating to the practice of chiroprody, proposes among other things, to enlarge the scope of a license to practice chiroprody. The bill proposes to permit chiroprodists to examine, diagnose or treat medically, mechanically, surgically or by electrical and manipulative means or by bandaging and strapping, the ailments of the human foot.

CONNECTICUT

Changes in Health Officers—Dr Harry B Smith has been appointed superintendent of health of the town of West Hartford succeeding Dr Theodore J Foster resigned. Dr Donald W Herrman has been named health officer of Winsted succeeding Dr Horace W Ward who had held the position since 1923 and Dr Louis Howard Wilcox succeeds Dr William H O Neil as health officer of Ansonia. Dr O Neil had occupied the position since 1928.

Bill Passed—S 456 has passed the senate, proposing to supplement the pharmacy practice act by providing that a store not a licensed pharmacy, which has been licensed to do so by the commission of pharmacy may sell proprietary and patent medicines if they are in sealed containers labeled and accompanied with directions for use and with the name and address of the manufacturer or distributor. Such patent and proprietary medicines however must not contain alcohol in excess of the amount necessary for use as a solvent or preservative and must not contain more than 2 grains of opium nor more than one fourth grain of morphine nor more than one eighth grain of heroin or 1 grain of codeine.

Sound Motion Pictures of Infant—The first public showing of sound motion pictures of the life and growth of the human infant produced by the Yale Clinic of Child Development was given in New Haven February 16. According to an announcement the films were assembled from scientific records collected by the clinic over a period of years and are intended for general educational and study purposes. The subjects include a description of the methods of studying infant behavior early and later stages in the growth of infant behavior posture and locomotion from creeping to walking, a baby's day at twelve weeks a thirty six weeks' behavior day a behavior day at forty-eight weeks, behavior patterns at one year learning and growth and early social behavior. The narration in the picture is by Dr Arnold L Gesell, director of the clinic.

FLORIDA

Mosquito Eradication and Malaria—The Florida board of health began a state-wide campaign of mosquito eradication in February. Cooperating with the board are representatives of the U S Public Health Service the bureau of entomology and the Rockefeller Foundation. In the first ten months in 1934, 330 deaths from malaria were reported, in 1933 the total was 373.

Society News—At a meeting of the Duval County Medical Society, March 5 a symposium on syphilis was presented by Drs Bertram F Woolsey, Alan D Brown, Lucien Y Dyrenforth, William W Kirk and James H Randolph. Dr Henry Hanson read a paper on 'Survey of the Maternal Mortality in Florida'. All are from Jacksonville. Dr David D Berlin, Boston, addressed the society, February 5 on 'Present Status of Total Thyroidectomy in the Treatment of Congestive and Anginal Heart Failure'. At a recent meeting of the Pasco-Hernando Citrus County Medical Society, Dr Samuel C Harvard, Brooksville, read a paper on 'Cancer of the Breast'. Speakers before the Dade County Medical Society in Miami, March 1, were Drs Marion C Wilson and Stewart Lee Jeffrey on endometriosis and dengue, respectively.

GEORGIA

Bill Passed—H 229 has passed the house, proposing to establish a special committee of the house and senate to formulate and to recommend to the next session adequate plans for the hospitalization of the indigent sick.

Personal—Dr Hugh B Senn Newberry S C, has succeeded Dr Guy G Lunsford, Millen, as health officer of Jenkins County. Dr Lunsford resigned to become chief of the division of county health work of the state department of health. Dr Herbert B Kennedy, Atlanta, has been appointed associate medical director of the Woodmen of the World, with headquarters at Omaha.

Hospital News—A new contagious disease and outpatient wing was recently added to the University Hospital of the University of Georgia, Augusta. A memorial gift of \$18,000 was presented to the institution by Mrs John W Herbert Augusta, to equip the addition, newspapers reported. The first floor of the new building, which was named for Milton Antony, founder of the medical school in 1828 is the outpatient department of the University Hospital, while the second floor is a contagious disease unit. Funds for the erection of the structure, which cost \$90,000, were obtained from the alumni association of the school of medicine a public works administration grant the city of Augusta and the county of Richmond.—The

Hamilton Memorial Hospital, Dalton, which has been closed for the past year was reopened March 4. Newspapers reported that the Civilian Hospital Board, Inc, will operate the institution.

IDAHO

Society News—Gordon E Davis of the staff of the laboratory of the U S Public Health Service at Hamilton, Mont, addressed the South Side Medical Society, Burley, February 18 on 'Results of the First Ten Years' Use of Spotted Fever Vaccine'. Dr William F Passer, Twin Falls, addressed the society, January 25, on "Anemia in Infancy and Childhood".

ILLINOIS

Society News—At the quarterly meeting of the Iowa and Illinois Central District Medical Association, Rock Island, March 15 Dr Emil Novak, Baltimore, discussed "Sex Differentiation and Intersexuality". Speakers before the LaSalle County Medical Society in Ottawa, March 20, were Drs Harry A Singer and George de Tarnowsky, Chicago, on "Ulcer and Cancer of the Stomach" and "Cancer of the Bowel and Its Surgical Management," respectively.—Health Promotion Week will be observed in Illinois, April 28-May 4.—Dr James H Hutton, Chicago, discussed 'Essential Hypertension and Diabetes Mellitus, Their Endocrine Aspects and Treatment by X Rays' before the Adams County Medical Society in Quincy, March 11. In the morning he conducted a clinical conference on essential hypertension before the society.—The St Clair County Medical Society was addressed in East St Louis, March 7, by Dr Williams McKim Marriott, St Louis, on 'Practical Points in Pediatrics'.—Dr Julius H Hess, Chicago addressed the Campaign County Medical Society, Campaign, recently on diagnosis of children's diseases.

Chicago

Society News—Speakers before the Chicago Urological Society, March 28 were Drs Eugene A Ockuly, Toledo, Ohio, among others on 'Osteomyelitis Following Lesions in the Genito-Urinary Tract'.—Dr Austin A Hayden discussed 'Hyperesthetic Rhinitis Ionization' before the Chicago Laryngological and Otolological Society, April 1.

Capps Prize Awarded to Dr Gulbrandsen—The Institute of Medicine of Chicago has awarded the Joseph A Capps Prize for 1934 to Dr Lars F Gulbrandsen, instructor in pathology, bacteriology and public health, University of Illinois College of Medicine, for a paper on 'Invasion of the Body Tissues by Orally Ingested Bacteria and the Defensive Mechanism of the Gastro-Intestinal Tract'. The prize of \$500, established by an anonymous donor in honor of Dr Joseph A Capps is awarded annually for the most meritorious medical research by a graduate of a medical school in Chicago completed within two years after graduation.

Personal—Dr Max Thorek was awarded the scrolled silver urn by the Hong Kong University of China at the recent international competition of camera art, for his picture "Odalisque," according to the Chicago Tribune.—Dr Clarence A Neymann sailed from New York, March 16, for Belgium, where he was invited as Committee for Relief of Belgium exchange professor to lecture at the Universities of Ghent, Louvain, Liège and Brussels on "Electrolytes in the Treatment of Disease". He will address the Royal Medical Society of London this month on the same subject.—Dr James P Henderson observed the completion of fifty years in the practice of medicine, March 10, his father Dr Harvey Dinwiddie Henderson, practiced medicine in Salem, Ind., for fifty-four years.

IOWA

Bill Introduced—S 336 proposes to repeal the law regulating the sale, distribution and possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

LOUISIANA

Personal—Dr Gideon Douglas Williams, Lake Providence, director of the East Carroll Parish health unit, has been appointed in charge of the Ouachita Parish health unit succeeding Dr John W Williams, Monroe, who resigned to become health director of Asheville, N C.—Dr James C Sartor, Rayville, has been appointed a member of the state board of health, succeeding the late Dr John L Kelly, Oak Grove.

University News—Bids will be opened this month for construction in New Orleans by Louisiana State University of a fifteen story dental and pharmacy school building, as a part of the medical center expansion program at the institution. Planned for occupancy next fall, the new building will be

erected on the grounds of Charity Hospital at a cost of \$2,500,000. It will be equipped with classrooms and laboratories for the teaching of dentistry, pharmacy, medicine and surgery. The expansion program will also include the rehabilitation of the hospital at a cost of \$8,000,000, it was stated.

MARYLAND

Bill Passed—S 211 has passed the house and the senate, proposing to authorize corporations to organize under the corporation laws of the state for the purpose of operating a non-profit hospital service plan.

Bill Enacted—H 70 has been enacted as chapter 59, Laws, 1935. This new law repeals the laws regulating the possession and distribution of narcotic drugs and enacts what the draftsman of the act cites as the 'uniform narcotic drug act.' The bill, however, differs from the model uniform narcotic drug act in some important particulars. It omits the provisions in the model bill intended to limit the gross quantity of a habit-forming drug a person can buy in exempt preparations within a period of forty-eight hours.

Child Health Conferences—A total of 9,749 children were examined in the child health conferences sponsored by the state department of health in 1934. Of these 2,490 were free from conditions in need of correction. 1,465 were underweight or gave other evidence of malnutrition, 3,492 needed dental attention. Unfavorable conditions of the lungs were noted in fifty-nine and of the heart in 245. In the 651 conferences held, 417 communities were represented. Medical treatments were not given but children needing care were referred to their own physicians and prompt correction was urged.

Birth and Deaths in 1934—There were 6,631 more births than deaths in Maryland in 1934, according to the state health department. For the year a total of 27,584 births was recorded and 20,953 deaths. There were twelve deaths in each thousand of the total population; this was offset by sixteen births, the report stated. The degenerative diseases of middle age and of the older age groups were responsible for 11,110 deaths, more than half of the total number at all ages and from all causes. Heart disease led the list of causes with a total of 4,502, then diseases of the kidneys, 2,347; cancer, 2,122; cerebral hemorrhage, 1,742; and diabetes, 397 deaths. Tuberculosis was responsible for 1,333.

MASSACHUSETTS

Communicable Diseases Decline—Figures released by the state health department to the newspapers indicate that communicable diseases notably decreased in 1934. There were 631 cases of diphtheria as compared with 1,041 for 1933. A new low point was noted for typhoid, with 135 cases as against 162. Only seventy-five cases of infantile paralysis were reported, as compared with 353 the previous year. Scarlet fever, with 8,393 cases, reached the lowest level recorded since 1922, and for the second consecutive year no smallpox was reported. Measles, however, on account of the widespread epidemic in the eastern half of the state in the early part of the year, reached the highest level ever recorded, with 44,818 cases. The percentage of deaths was lower than ever previously recorded except in 1933.

Society News—The Massachusetts Medical Society is making a survey of the adequacy of medical service in the state. When the data have been tabulated from questionnaires, a report will be published.—Dr Paul R. Withington, Milton, was elected president of the Massachusetts Association of Boards of Health at its annual meeting, January 31.—Speakers before the New England Heart Association in Boston, March 25, included Drs Maurice A. Lesser on 'Primary Bilateral Pulmonary Thrombosis' and Frederick H. Pratt 'A Transitional Region Between Skeletal and Cardiac Muscle.'—Speakers before the Springfield Academy of Medicine, February 12, were Drs Rosco G. Leland, Chicago, and Nathan B. Van Etten, New York, on medical economics.—A symposium on the surgical treatment of pulmonary tuberculosis constituted the program of the Plymouth District Medical Society, March 21; speakers were Drs Bradford H. Pierce, Roy F. Littlehale, John A. McCarthv, Ebenezer K. Jenkins, South Hanson, and George A. Moore, Brockton.—Dr Jacob Kaminsky, Waltham, addressed the Middlesex East District Medical Association, March 13, on 'Physiopathologic Factors in the Treatment of Pulmonary Tuberculosis.'—The Harvard Medical Society was addressed, March 26, by Drs Joseph T. Wearn, Cleveland, on 'The Circulation in Normal and Hypertrophied Hearts' and Claude S. Beck, Cleveland, 'Establishment of Collateral Blood Channels to the Heart by Operation.'

MICHIGAN

Graduate Courses—The Michigan State Medical Society and the department of graduate medicine of the University of Michigan, Ann Arbor, are cooperating in a series of graduate courses, which began April 1. The courses will cover electrocardiographic diagnosis, surgery and diseases of the blood and blood-forming organs among other subjects, and will extend over a period of several weeks.

Society News—Dr Cleveland J. White, Chicago, addressed the Calhoun County Medical Society, March 5, on 'Diagnosis and Modern Treatment of Eczematoid Eruptions of the Skin, with Special Reference to Ringworm and Allergic Dermatitis.'—George E. Brand, LL.B., president of the Detroit Bar Association, addressed a joint meeting of this group with the Wayne County Medical Society, February 25, in Detroit; his subject was 'Common Problems Facing Law and Medicine.' The medical society devoted its meeting, March 18, to a symposium on tuberculosis; speakers were Drs Bruce H. Douglas, Eldwin R. Witwer and Willard B. Howes.—Dr Arthur E. Schiller, Detroit, addressed the East Side Physicians' Association, March 14, on 'Allergy in Skin Diseases.'

Cancer Survey—The prevalence of cancer in rural areas in Michigan will be determined in a survey to be undertaken by the state department of health under a grant from the U. S. Public Health Service. Only full time county or district health departments will be included in the survey, which will be carried out by Dr Harold Kessler, Alpena. Practicing physicians will be consulted to ascertain such information as the number of cases of cancer known to them, age and sex distribution, and the location and type of the lesion. This survey follows one recently carried on in hospitals by Dr Frank L. Rector, field representative, American Society for the Control of Cancer.

MINNESOTA

Symposium on Malignancy—The annual symposium on malignancy of the Minneapolis Surgical Society was held at the auditorium of the Hennepin County Medical Society, April 4. Drs Martin Nordland, president, and Kenneth Bulkley, chairman, made introductory remarks and the scientific program was presented by the following physicians:

Stephen H. Baxter, Melanoma
Martin Nordland, Malignancy of the Thyroid
Theodore H. Sweetser, Malignancy of the Urinary Tract.
Frederick A. Olson, Organization of Hospital Service for Diagnosis and Treatment of Malignancy
Stanley R. Maxeiner, Carcinoma of the Stomach
James A. Johnson, Treatment of Carcinoma of the Rectum by Cautery in Patients of Advanced Age and Other Poor Surgical Risks

Dr Frederick A. Olson was elected president of the society recently. Dr Richard R. Cranmer, vice president, and Dr Edward A. Regnier, secretary.

MISSISSIPPI

Personal—Dr John C. McGuire, at various times in charge of county health departments in Kentucky, has been named full time director of the Copiah County Health Department, succeeding Dr James T. Gooze, who recently resigned to become assistant state health director of Florida.

Trend of Death Rates—Death rates from the five major preventable diseases and the five major causes of death not subject directly to public health control for the period 1914-1933, were recently studied by the Mississippi Board of Health. In the former group (tuberculosis, malaria, pellagra, typhoid and diphtheria) a total of 5,530 deaths was recorded in 1914 against 2,546 in 1933, a decrease of 54 per cent. In the group not subject to public health control (heart disease, nephritis, cancer, homicide and automobile accidents), 3,276 deaths were reported in 1914 as against 5,346 in 1933, an increase of 63 per cent. The board points out that a comparison of the two groups shows that deaths from the five causes not under public health control are increasing at a rate 9 per cent faster than the deaths from the five preventable diseases are decreasing.

MISSOURI

Medical Library—The library of the late Dr Jacob Geiger, professor emeritus of surgery, St. Louis University School of Medicine, will form the nucleus of a medical library now being planned by the Buchanan County Medical Society. Dr Geiger's collection has been donated to the society by his family. The late physician was dean and professor of surgery at Ensforth Medical College from 1883 to 1914 and a past president of the Missouri State Medical Association.

Memorial to Dr Jackson—The Jackson County Medical Society met at the Kansas City General Hospital, Kansas City, March 26, to honor the memory of Dr Jabez N. Jackson.

who died March 18. Speakers included Judge James F. Goodrich who spoke on 'Julius Jackson, Surgeon and Citizen,' and the following physicians:

Frank C. Neff His Influence on Local Medicine
Frank D. Dickson His Personal Qualities and Character
Frank A. Teichner His Influence on National Medicine
John M. Frankenburg His Hobbies and Recreations
Ruford G. Hamilton President of the American Medical Association

Dr. Doisy Awarded Medal—The St. Louis Medical Society presented a medal and certificate of award to Edward A. Doisy, Ph.D., professor of biochemistry, St. Louis University School of Medicine at a meeting March 19. Dr. Doisy is known particularly for his work on the estrogenic hormones and for the isolation and preparation of the same. Philip A. Shaffer, Ph.D., professor of biological chemistry, Washington University School of Medicine, St. Louis made an address before the medal was presented. The award of merit was established by the society in 1925. The recipient must be recommended by the medical faculties of both St. Louis and Washington universities and must be unanimously elected by open vote of the council at the annual meeting. The last award was made in 1927, when it was given jointly to Drs. I. Warts A. Graham, Glover H. Copher, Warren H. Cole and Sherwood Moore in recognition of their work on gallbladder visualization.

NEBRASKA

Society News—Dr. Ralph A. Reis, Chicago, addressed the Lancaster County Medical Society, Lincoln, March 5 on 'Some Aspects of the Conduct of Normal Labor.'—Dr. Chester Q. Thompson, Omaha, among others, addressed the Tri County Medical Society of Dodge, Washington and Burt counties, February 25, on blood transfusion.—Drs. Floyd S. Clarke and Gustave W. Dishong, Omaha, addressed the Southwestern Nebraska Medical Society, February 14 in McCook on 'Nephritis in Children' and 'The Nervous Patient and the Physician,' respectively.—Dr. Emil Novak, Baltimore, addressed the Omaha-Douglas County Medical Society, Omaha, March 6, on 'The Endocrines in Gynecology and Obstetrics.'

NEVADA

Annual Registration Due May 1—All persons holding licenses to practice medicine in Nevada are required by law to pay annually to the treasurer of the board of medical examiners, on or before May 1 a tax of \$2. Failure to do so operates to forfeit a licensee's right to practice medicine and his license can be reinstated thereafter only on the payment of a \$10 penalty.

NEW JERSEY

Graduate Course in Endocrinology—Drs. Roy G. Hoskins, director of research, Memorial Foundation for Neuro-Endocrine Research, Harvard University Medical School, Boston, and Joseph M. Looney, director of laboratories, Memorial Foundation for Neuro-Endocrine Research, Worcester State Hospital, Worcester, Mass., conducted a graduate course in endocrinology, sponsored by the Somerset County Medical Society, the state medical society and Rutgers University in February and March. Two sessions each were held in Skillman and Trenton, one each in Marlboro and Morristown.

NEW YORK

Bill Enacted—A 445 has been enacted as chapter 266, Laws 1935, safeguarding the distribution of dangerous caustic or corrosive substances as defined in the federal caustic poison act, by requiring their labeling as poison.

Bills Passed—A 1861 has passed the assembly, proposing to amend the laws relating to the practice of chiropody by designating the practice of chiropody as the practice of podiatry and by creating an independent board of podiatry examiners. S 1816 has passed the senate, proposing to accord to charitable and governmental hospitals treating persons injured through the fault of others liens on all claims rights of action, judgments settlements or compromises accruing to the injured persons by reason of their injuries.

Buffalo Alumni Meeting—The annual spring clinical day of the Alumni Association of the University of Buffalo School of Medicine will be held April 20. Following is the program:

Dr. William Wayne Babcock Philadelphia Improvement in Management of Appendicitis
Dr. Udo J. Wile Ann Arbor Mich. Skin Manifestations of Idiopathic Crazy to Common Drugs
Dr. Foster Kennedy New York Relation of Neurology and Psychiatry to General Medicine
Dr. Julius H. Hess Chicago Chronic Intestinal Indigestion in Children Celiac Disease
Dr. Russell L. Haden Cleveland Agranulocytosis
Dr. P. Brooke Bland Philadelphia Uterine Hemorrhage

New York City

Alumni Reunion—Alumni Day will be held at Long Island College of Medicine, Brooklyn, April 27. At the morning session Dr. Paul A. O'Leary, Rochester, Minn., will speak on 'Modern Treatment of Syphilis', at luncheon Dr. Henry Wallace of the class of 1890 will give reminiscences and at the annual banquet in the evening the speaker will be Dr. William Alanson White, superintendent, St. Elizabeth's Hospital, Washington, D. C.

Sentenced for Defrauding Students—Two men were convicted recently of obtaining \$500 from one premedical student and \$900 from another by promising to have them admitted to medical schools. Beard John Dupree was sentenced to a term of from six months to three years in the New York County Penitentiary and Martin J. Phillips, a term of three months in the workhouse. During their trial, signed agreements between the defendants and the students were produced in evidence, containing legal contracts for these services. The scheme was exposed through the activities of Prof. William C. MacTavish of New York University.

Society News—Speakers before the Medical Society of the County of New York, March 25, were Louis I. Dublin, Ph.D., on 'Favorable Aspects of Heart Disease', Dr. John R. Paul, New Haven, Conn., 'Rheumatic Heart Disease' and Dr. Paul D. White, Boston, 'Coronary Disease and Coronary Thrombosis in Youth'.—Speakers at a meeting of the International and Spanish-Speaking Association of Physicians, Dentists and Pharmacists, March 23 were Drs. Emil Novak, Baltimore, on 'Sterility and Endocrines', Frederic Bierhoff, 'Impotence in the Adult and Adolescent', Charles F. Geschickter, Baltimore, 'The Breast and the Sex Hormones' and Gerard L. Moench, 'The Problem of Human Sterility'.—The meeting of the Bronx County Medical Society, March 20, was devoted to discussions of fractures by Drs. Edward R. Cunniffe, Milton R. Bookman, Edwin A. Spies and Samuel Kleinberg.

Group Hospitalization Plan—The United Hospital Fund announces completion of plans for launching a group hospitalization plan among approved hospitals in the metropolitan area. Frank Van Dyk, manager of the Associated Hospitals of Essex County, Newark, N. J., has been named executive head of the plan, which will be operated by the Associated Hospital Service of New York, a new nonprofit corporation organized under the auspices of the United Hospital Fund. Salaried persons and wage earners are eligible to participate, their dependents may be included later, it was said. The cost will be \$10 a year entitling the subscriber to three weeks of semiprivate hospital care on recommendation of his private physician. The physicians fee is not included. The new plan is the result of two years' study by a committee appointed in December 1932. Officers of the governing organization are Karl Eilers, president of Lenox Hill Hospital, president Stanley Resor, member of the board of Manhattan Eye, Ear and Throat Hospital, and Dr. Walter T. Dannreuther, vice presidents, and Homer Wickenden, general director of the United Hospital Fund, secretary. More than fifty hospitals have been accepted for charter membership, it was announced April 1.

NORTH CAROLINA

Bills Introduced—H 769, to amend the osteopathic practice act, proposes to permit osteopaths to dispense and prescribe drugs. S 411 proposes to prohibit the sale of bichloride of mercury except on prescription of a person licensed to write prescriptions. H 829, to amend the medical practice act proposes, in effect to permit the board of medical examiners to hold their meetings in whatever city or cities in the state they desire. The present law requires at least one meeting annually to be held in Raleigh.

OKLAHOMA

Personal—Dr. Allen C. Kramer, Tulsa, has been appointed health officer of Tulsa County, succeeding Dr. Thomas W. Stallings.—Dr. Ernest L. Bagby, Vinita, has been appointed superintendent of the Oklahoma Institution for the Feeble-minded. Enid. Dr. Bagby was formerly superintendent of the Western Oklahoma Hospital, Supply.

Bills Introduced—S 349 to amend the medical practice act, proposes (1) to require the board of medical examiners to hold regular meetings on the second Wednesday in June and December of each year, rather than the second Tuesday in March and September and (2) to authorize the board to revoke the license of any licensee who has been convicted of any felony in or without the state of Oklahoma, rather than

as the present law provides, authorizing it to revoke the license of any licentiate who is serving a penalty on a felony or of any offense involving moral turpitude S 347 proposes to repeal the law regulating the sale, distribution and possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act

OREGON

The Oregon Pharmacy Act—THE JOURNAL, March 9, commented on the provision of the Oregon pharmacy practice act, approved February 21, 1935 (Laws, 1935, ch 55), that nothing in it should be construed to prevent the personal administration of drugs and medicines carried by physicians dentists or veterinarians, "to supply the immediate needs of their patients." The chairman of the legislative committee of the Oregon State Pharmaceutical Association calls attention to another provision that nothing in the act shall interfere with licensed physicians and dentists supplying their own patients with such remedies as they may desire, provided that the physician or dentist does not keep a pharmacy or drug store. The provision authorizing practitioners of medicine or dentistry to supply remedies to their patients will presumably be construed to supplement and broaden the provision that limits physicians and dentists to the personal administration of drugs and medicines carried by them.

PENNSYLVANIA

District Meeting—Dr Morris Fishbein Chicago editor of THE JOURNAL will give an address at the annual banquet of the Tenth Council District Meeting of the Medical Society of the State of Pennsylvania in Beaver Falls, May 9 on "Plans for Social Security." Among speakers at the scientific sessions will be Drs Bernard Fantus Chicago on "The Therapy of Colon Stasis," and Richard B Cattell, Boston, "Diagnosis and Treatment of Cancer of the Colon and Rectum."

Bills Introduced—S 769, to amend the medical practice act, proposes (1) to designate the Bureau of Medical Education and Licensure as the Board of Medical Education and Licensure, (2) to require an applicant for a license to be a high school graduate and to have had two years (rather than one year) of college credits in chemistry, biology and physics prior to medical study, (3) to require an applicant to have had one year of internship but to eliminate the provision in the present law which requires that during that year of internship the applicant must have attended or participated in attending not less than six confinements, (4) to require "applicants foreign to the territory of the United States" to "present a certificate of United States citizenship or a declaration of intention" (5) to provide that the provisions of the act shall not apply to any one actually serving as a "student intern under the supervision of the medical or surgical staff of any legally incorporated hospital" and to provide that the act shall be construed as applying to hospitals employing on salary graduate interns whose services are confined to said institutions when they assume individual responsibility in the care of patients", and (6) to permit the board to revoke or suspend a license "upon satisfactory proof of grossly unethical practice, of misleading public advertisements, or of any form of pretense which might induce citizens to become a prey to professional exploitation." H 1959 proposes a system of compulsory and voluntary sickness insurance. The benefits proposed are to consist of cash and all forms of medical and dental service. Persons employed at other than manual labor" and receiving wages in excess of \$60 a week, farm laborers and persons employed by an employer having less than three employees in personal or domestic service are excluded from the compulsory insurance of the bill but are entitled to participate in the voluntary insurance. H 1759, to amend the medical practice act, proposes to require the bureau of medical education and licensure to license, after examination, practitioners of various schools of drugless therapy, enumerating specifically practitioners of chiropractic, naprath, "spondylotherapy, suggestive therapeutics, metaphysics, vita therapy, magnetic healing, naturopathy and physiotherapy." The bureau is to appoint three persons now licensed in drugless therapy from a list of seven names submitted by the Pennsylvania Association of Licensed Drugless Therapists, who are to conduct such examinations as in their judgment they deem necessary to determine the fitness of the particular applicant. H 1772 proposes to make it a ground for divorce for either spouse to be hopelessly and incurably insane." H 1730 proposes to require state-aided hospitals to admit any indigent person who is seriously ill and who requires hospitalization. Every state-aided hospital caring for such an indigent person is to be compensated by the state.

Philadelphia

Medical College News—Charles-Edward Amory Winslow, Dr P H, Anna M R Lauder professor of public health, Yale University School of Medicine, New Haven, Conn., delivered the Potter Memorial Lecture at Jefferson Medical College, March 29, on "A Physician of Two Centuries Ago Richard Mead and His Contributions to Epidemiology."

Anniversary of Maimonides—The chapters of Phi Delta Epsilon and Phi Lambda Kappa at the University of Pennsylvania, Temple University, Jefferson Medical College and Hahnemann Medical College sponsored a public meeting, March 30, to celebrate the octocentennial anniversary of the birth of Maimonides. Speakers were Dr Victor Robinson, New York, on "Maimonides the Physician," Rabbi William H Fine "Schreiber Maimonides the Rabbi," and Isaac Husik, Ph.D., professor of philosophy, University of Pennsylvania, "Maimonides the Philosopher."

Swindler Voluntarily Dislocates Vertebra—A Philadelphia hospital reports the case of a man who sought medical attention for alleged injury received in a fall from a bus. Roentgen and clinical examination revealed a dislocation of the first cervical vertebra. The man refused morphine and anesthesia insisting that the dislocation be reduced without either. He was placed in bed with traction and it was planned to make a cast in a few days. During the period of traction he communicated with the bus company and demanded \$10,000 damages but suddenly settled his claim for \$200. He then got out of bed left the hospital and has not been heard of since. Investigation by the bus company revealed a long police record under a variety of names. In Philadelphia he gave the name James L Carter of Oakland, Calif., and a companion claimed to be his brother. San Francisco authorities sent a photograph of one Donald Carlyle who was identified in Philadelphia as Carter. In California he had collected \$60 from a street car company because of an alleged injury to his wrist. Under the name of Albert Monroe he had received \$250 on a fraudulent claim from a bus company in Los Angeles. The records indicated that he had been arrested other times on the Pacific Coast, as well as in St Paul and that he was wanted in Washington, D C in connection with a forgery under the name Donald Del Ruth. Other aliases listed in San Francisco include Patrick J Holley, Buddy Ryan, Pat Ryan, C. Malone and Ben F Tilley. Carter is from 25 to 30 years old, 6 feet tall with brown hair. He is smooth shaven and weighs about 160 pounds. He said he was a photographer. His companion is from 22 to 25 years old about 5 feet 7 inches tall, with dark brown hair, and weighs about 140 pounds. None of the records show that this man has presented a dislocation of the neck in any of his former activities, but the physicians who attended him in Philadelphia were of the opinion that this was not his initial performance.

Pittsburgh

Annual Meeting—The Allegheny County Medical Society held its annual meeting at the Hotel Schenley, April 2. After demonstrations of allergic patients Dr William V Mullin, Cleveland, discussed "Treatment of Sinus Disease, with Particular Reference to Allergy of the Upper Respiratory Tract." At the banquet in the evening Dr Howard W Haggard, associate professor of physiology, Yale University, made an address on "Medicine and the Public."

SOUTH CAROLINA

Bill Passed—S 204 has passed the senate and the house, proposing to amend the insurance law so as to authorize any ten or more persons to associate themselves together as a mutual protection association for the indemnifying of each other for losses on the assessment plan, and not for profit, "to insure the lives or health of members against death or disability by accident or disease, or hospitalization benefits."

Special Meeting of House of Delegates—The house of delegates of the South Carolina Medical Association held a special meeting in Columbia, March 5, to hear the report of delegates to the special meeting of the House of Delegates of the American Medical Association. The report of the reference committee at the Chicago meeting was unanimously endorsed and a committee was appointed to act in cooperation with the American Medical Association and committees from other state associations in the study of economic problems. The committee includes Drs Robert S Cathcart, Charleston, James W Jervey Greenville, Thomas A Pitts, Columbia, Charles R May, Bennettsville, and William R Wallace Chester.

State Medical Meeting in Florence—The eighty-seventh annual session of the South Carolina Medical Association will be held in Florence, April 23-25. Invited guests will be Drs.

Henriens J Stander New York, who will speak on 'Nephritis in Pregnancy' William B Castle, Boston, 'Diagnosis and Treatment of Anemia and Certain Associated Deficiency Diseases,' and Temple S Fay, Philadelphia 'Head Injuries Their Management and Treatment' South Carolina physicians listed on the preliminary program include

Dr James Richard Allison Columbia The Practical Management of Acne Vulgaris
Dr Kenneth M Lynch Charleston Malignant Melanoma
Dr Lucius Emmett Madden Columbia Suppurative Pericarditis
Dr George T Tyler Jr Greenville Sulphureous Abscess
Dr Olin B Chamberlain Charleston, Early Diagnosis of Chronic Arthritis
Dr Austin T Moore Columbia Fracture of the Hip Joint (Intra capsular)—A New Method of Skeletal Fixation

The South Carolina Public Health Association will hold its meeting April 23 and the women's meeting, April 24

WISCONSIN

Bill Introduced—A 1933 proposes to make it the duty of the county board of supervisors of every county to provide medical, dental and hospital care and treatment for all persons receiving relief in the county and to set aside such funds as may be necessary to preserve the health of such persons

Personal—Dr Charlotte J Calvert, supervisor of the bureau of child welfare of the state board of health since 1929 and a member of the staff since 1925, retired to private life March 1 —Dr John C Wright, Autigo was made honorary secretary of the Langlade County Medical Society on his retirement in February as active secretary after many years service

Fellowships for Research in Cancer—Drs Fred L Mohs and Harold P Rusch, Madison have been appointed to research fellowships at the University of Wisconsin School of Medicine under the fund recently left to the university by Miss Jennie Bowman A special committee is investigating the possibility of expanding cancer research at the university under the \$450,000 bequest, which at present yields an income of \$12,000 a year

Society News—Dr Herman L Kretschmer, Chicago, addressed the Milwaukee Roentgen Ray Society in Milwaukee, February 1, on 'Roentgen-Ray Problems in Pediatric Urology' —At a meeting of the Milwaukee Society of Clinical Surgery, February 25, speakers were Drs Herman A Heise, Milwaukee, on 'Blood Transfusion in Emergency Surgery,' Ralph M Waters, Madison, 'Anesthesia in Emergency Cases' and Frederick A Besley Waukegan Ill 'Treatment of Compound Fractures' —Dr Morris Fishbein, Chicago editor of THE JOURNAL, addressed the Brown-Kewaunee-Door Counties Medical Society, Green Bay, February 9, on 'Our Changing Times'

PUERTO RICO

Tuberculosis Clinic on Wheels—The health department of Puerto Rico has had built a special 1½ ton Dodge truck for use in its tuberculosis service There is a compartment containing the x-ray apparatus and a special cot for the patient while being photographed In this compartment also are the developing tanks which may be made light proof by means of special shutters, and storage space for photographic plates In the rear of the truck are cabinets and drawers for storing medical supplies a 30 gallon water tank and a sink A motor driven fan supplies fresh air to both sections of the truck, and a special generator driven from the transmission take-off furnishes electric power for the x-ray machine

GENERAL

Society News—The American Heart Association will meet in Atlantic City June 11 and not June 6 as noted in THE JOURNAL, April 6 —The National Congress of Parents and Teachers will hold its annual meeting in Miami, Fla., April 29 May 3 —The American Urological Association will meet in San Francisco, June 25 28, in conjunction with the Western Branch Society

Anatomists Meet in St Louis—The American Association of Anatomists will hold its fifty-first session at Washington University School of Medicine, St Louis April 18-20 Dr Warren H Lewis Baltimore, will deliver his presidential address at the annual banquet at the Hotel Chase Friday evening, April 19, on 'Normal and Malignant Cells A feature of the program will be a symposium on 'The Relation of the Pituitary to Reproduction,' presented by Aura E Severinghaus Ph D New York Frederick L Hisaw Ph D Madison Wis, Carl R Moore, Ph D, Chicago, and Warren O Nelson Ph D, Chicago

Another Impostor—A man using the name Maguire is reported to have called on physicians in several cities attempting to borrow money Introducing himself as the brother-in-law of Dr Winford H Smith, director of the Johns Hopkins Hospital, Baltimore, he tells of an automobile accident and a fine that has taken all his cash He asks for a small loan to enable him to reach home He is described as being between 60 and 65 years of age, with thin light hair and eyes, and neatly dressed A small wrinkle or scar runs downward and outward about an inch from the right side of the mouth Several teeth are missing from his right lower jaw, leaving a conspicuous discolored canine tooth He is said to have operated in Rochester, N Y, Columbus Ohio, and Montreal within the past year

A Film to Instruct Mothers—"Around the Clock with You and Your Baby" is the title of a motion picture to educate mothers in the care of the new-born, produced by the department of obstetrics and gynecology of the University of Southern California at Los Angeles under the direction of Drs Lyle G McNeile and Donald G Tollefson The care and feeding of infants as it should be done in the average home, as well as advice for mothers own health, is shown in detail The film 35 mm in three reels, requires about thirty-five minutes to show It may be lent without charge for an indefinite time to any ethical hospital, if shown at least twice a week and a report of the number of showings and the number of persons who viewed the film is forwarded once a month Further information may be obtained by writing Dr Tollefson, 511 South Bonnie Brae Street, Los Angeles

Immigrant Physicians in 1934—Records of the U S Bureau of Immigration show that during the fiscal year ended June 30, 1934 the United States admitted 353 immigrant aliens who gave their occupation as physician Although the number of all immigrants has been reduced from 279,678 in 1929 to 29,470 in 1934, the number of physicians in 1934 was almost as great as that for 1929, 398 For the intervening years the numbers were 390 in 1930 329 in 1931, 259 in 1932, and 187 in 1933 By far the greatest number (160) came from Germany in 1934 and the greatest number to settle in any one place remained in New York, 190 Among the group were 163 Jewish physicians American consular officers abroad, who must determine in each case whether a prospective immigrant is admissible to the United States, may allow a physician to enter the United States in his professional capacity even if the quota restrictions are exhausted, but he is required to present proof that he has sufficient income and resources to keep him from becoming a public charge

American College of Physicians—The nineteenth annual clinical session of the American College of Physicians will be held in Philadelphia, April 29-May 3, with general headquarters at the Municipal Auditorium A clinical program will make up the general sessions, to be held at eleven hospitals and some of the medical schools in the city A departure this year is a series of morning lectures, which, according to the program, is presented as an elective, as a whole or for individual days in place of the hospital clinics These lectures will be presented daily and will be devoted to four general topics diseases of the bones and joints, neurology, bronchopulmonary diseases and endocrinology The annual convocation will be held Wednesday evening May 1, when the John Phillips Memorial Medal will be presented Following the convocation ceremony Dr Leo Loeb, professor of pathology Washington University School of Medicine, St Louis, will speak on 'The Thyroid-Stimulating Hormone of the Anterior Pituitary Gland,' and Dr Jonathan C Meakins Montreal, will deliver his presidential address There will be a smoker, Monday evening, and the annual banquet will be held Thursday evening On the latter occasion, Dr Alfred Stengel, Philadelphia, will be toastmaster, and Hon Roland S Morris, president, American Philosophical Society and ex-ambassador to Japan will give an address on 'The Present Unrest in the Far East' With special emphasis placed on clinics, the program this year gives a place to consideration of the fundamental aspects of physiology and biochemistry besides the more practical problems of medicine

Medical Bills in Congress—Changes in Status H R 7260 introduced by Representative Doughton, North Carolina April 4 and reported to the House, April 5, with recommendation that it pass is a redraft of the so-called Wagner-Doughton-Lewis Social Security Bill The redraft omits from its title all reference to 'illness' The original social security bill proposed to establish a Social Insurance Board, which, among other things, was to be authorized to make recommendations with respect to health insurance In the redraft of the bill the name of the board has been changed to 'Social Security Board,' and no duty devolves on the board to study and make recommendations specifically with respect to health insurance

Government Services

Corporations organized and operated exclusively for religious, charitable, scientific, literary or educational purposes no part of the net earnings of which inures to the benefit of any private shareholder or individual, are not liable to the assessments provided in the redraft for old age or unemployment benefits, nor, apparently, are employees of such corporations to be entitled to such benefits. The redraft provides, as did the original bill, federal subsidies, contingent on state plans being acceptable to federal agencies, to promote material and infant welfare, to care for crippled or dependent children, to provide for child welfare services, and for the development of state and local health work. **Bills Introduced** H R 7124, introduced (by request) by Representative Hennings, Missouri, proposes to authorize the erection of an addition to the existing veterans facility at Jefferson Barracks, Missouri. H R 7130, introduced by Representative Nichols, Oklahoma, proposes to authorize the erection of additional facilities to the existing veterans' facility at Muskogee, Okla. H R 7134, introduced by Representative Utterback, Iowa, proposes to authorize the erection of an addition to the existing veterans facility at Knoxville, Iowa. H R 7135 introduced by Representative Gulmer, South Carolina, proposes to authorize the erection of an addition to the existing veterans facility at Columbia. S C H R 7156 introduced by Representative Scringham, Nevada, and S 2455 introduced by Senator McCarran, Nevada, propose to authorize the erection of a veterans hospital in Nevada. H R 7163, introduced by Representative Fenerty, Pennsylvania, proposes to authorize the erection of an addition to the existing veterans' facility in the District of Columbia. H R 7169 introduced by Representative Church, Illinois, proposes to erect an addition to the existing veterans' facility at North Chicago, Ill. H R 7200 introduced by Representative Kinzer, Pennsylvania, proposes to erect an addition to the existing veterans' facility at Coatesville, Pa. H R 7232 introduced by Representative West, Texas, proposes to erect a veterans hospital in Texas. H R 7234 introduced (by request) by Representative Christianson, Minnesota, proposes to authorize the erection of an addition to the existing veterans facility at Minneapolis. H R 7261, introduced by Representative Carter, California, proposes to authorize the erection of an addition to the existing veterans facility at Livermore, Calif.

FOREIGN

New Editor of Tuberculosis Journal—Dr Lancelot S. T. Burrell was recently appointed editor of the *British Journal of Tuberculosis* and various changes in the form of the publication have been made beginning with the January issue. It will be the policy henceforth to emphasize the practical as opposed to the purely theoretical, according to an announcement. A department to be known as 'Consultations,' and another, 'Problems in Applied Medicine,' are now included in addition to original articles, society proceedings, abstracts and book reviews.

Chadwick Medal Awarded—Col. William P. MacArthur, late of the Royal Army Medical Corps, received, February 18, the Chadwick Gold Medal and Prize of £100 awarded every five years to the medical officer of the navy, army or air force who has most distinguished himself during that period in promoting the health of the men of the service to which he belongs. Following the ceremony, the twenty-third annual series of Chadwick Lectures was inaugurated by W. A. Robson, barrister-at-law, with an address on the evolution of public health during the past hundred years.

Congress on Industrial Accidents—The American delegation to the seventh International Congress on Industrial Accidents and Diseases to be held in Brussels, Belgium, July 22-27, will leave New York July 8 and will visit London, Amsterdam, The Hague, Paris, and optionally Budapest. Physicians interested in the congress or in the medical tour may receive information from the secretary for America, Dr. Richard Kovacs, 1100 Park Avenue, New York. Dr. Fred H. Albee, New York, is chairman of the American committee for the section on accidents and Dr. Emory R. Hayhurst, Columbus, Ohio, for industrial diseases.

CORRECTIONS

Antirachitic Cow's Milk—In the article by Gerstenberger, Horesh, Van Horn, Krauss and Bethke in *THE JOURNAL*, March 9, the heading of table 6, on page 817, should have read Comparative Vitamin D Potencies of Butter Fat from Y Milk and from L Milk (Curative Method).

Months Instead of Years—On page 998 of the article by Dr. Novak in *THE JOURNAL*, March 23, the statement that Engelbach reported satisfactory growth results in a pituitary dwarf in whom treatment was carried out 'for nine and a half years' should read 'for nine and a half months'.

Increase of 6,264 Patients in Veterans' Hospitals

Continuous adjustments in benefits authorized to war veterans and their dependents were in process during the fiscal year ended June 30, 1934, according to the annual report of the Veterans' Administration. Changes brought about under the law enacted March 20, 1933, had been placed in operation when the statute of March 28, 1934, was enacted, restoring many of the provisions that had been in effect before the Economy Act. The Board of Veterans' Appeals, established Dec. 1, 1933 to review claims, had rendered decisions in 7,523 cases and had pending 7,358 at the end of the fiscal year. The total hospital load of the Veterans' Administration at the close of the year was 40,059, an increase of 6,264 over the previous year, largely the result of liberalization of the provisions of the Economy Act. The entire increase occurred in the group of patients with non-service connected disabilities. The report states that with the exception of 1932 this patient population is the highest recorded in any year since 1917, when hospitalization for World War veterans was first authorized. Classified according to service there were among the patients 35,754 veterans of the World War, 2,229 Spanish American War, 194 Civil War, 97, other wars and expeditions, and 1,171 peace time service. Of the World War veterans only 11,799 were being treated for disabilities of service origin. Of all patients in the hospitals 56 per cent were suffering from neuropsychiatric diseases, 13 per cent from tuberculosis and 31 per cent from general medical and surgical conditions. In June 1923 the percentages were respectively 39, 41 and 20. The number of hospital admissions during the year was 63,900, the lowest recorded since 1920. The drop was due to the law of March 20, 1933 which denied hospitalization for non-service connected disabilities of a temporary nature, operations of choice and similar conditions. During the last part of the year following the enactment of the more liberal law of March 1934 there was a material increase, it was said. Of the admissions 42,475 were for general medical and surgical conditions, 8,889 for pulmonary tuberculosis, 5,695 for psychotic and mental diseases and 6,841 for other neuropsychiatric disorders. The total number of patients in the various hospitals during the year was 108,676, of whom 58,713 were discharged after an average of 122.1 inpatient days. Deaths totaled 5,334 of which 2,901 occurred among patients under treatment for general conditions, 1,660 for pulmonary tuberculosis, and 773 for neuropsychiatric diseases. Of those among general patients, more than 38 per cent were caused by diseases of the circulatory system and approximately 30 per cent by malignant tumors and diseases of the genito-urinary system. The veteran population under domiciliary care at the end of the fiscal year totaled 9,404 as compared with 11,187 the previous year. There were 8,305 admissions of which 85 per cent were for non-service connected disabilities and 9,806 discharges after an average period of five months' care. The total number of beds controlled by the Veterans' Administration in both hospital and domiciliary facilities June 30, 1934, was 66,839. Seven new facilities were opened with beds as follows: Fayetteville, Ark. 258; Des Moines, Iowa, 300; Wichita, Kan., 166; Biloxi, Miss. 207; Batavia, N. Y., 297; Roseburg, Ore., 191; and Cheyenne, Wyo., 108. Domiciliary facilities were opened at Biloxi and Roseburg, with 350 beds each. Since the end of the year under report, two facilities have been completed at San Francisco, 334 beds, and at Roanoke, Va., 472 beds. Plans were approved for conversion of the facility at Danville, Ill., into a neuropsychiatric hospital. The field facilities of the administration made 559,554 physical examinations for outpatient purposes, a decrease of 790,898 from the previous year. Treatments furnished totaled 575,816 as compared with 830,115 the previous year. As a result of the Economy Act of March 20, 1933, the number of emergency officers of the World War entitled to retirement pay was reduced from 6,304 to 1,595, the law having limited this benefit to those whose disabilities resulted directly from military or naval service. The net operating expense for all hospitals was \$32,620,447.39, and for domiciliary facilities \$3,648,607.60. The per diem cost of operation for hospitals was estimated to be \$2.51, and for domiciliary facilities 97 cents. The actual net disbursements of the administration for all purposes during the year aggregated \$594,022,058.08. At the end of the year there were 34,890 employees on the rolls, 5,210 in the central office and 29,770 at field stations whose gross annual salaries amounted to \$55,810,584.

The Aging of the English Population

Again the figures of the registrar general show that as a people the English are growing older as a result of the falling birth and death rates. The birth rate for 1934 was 148 per thousand of population. In the last thirty odd years the rate has been halved. This fall is without parallel in the history of this or any other country. The infant death rate in 1934 was 59 per thousand live births. In the quinquennium 1901-1905 it was 138. The general death rate has also been falling steadily. In the quinquennium 1901-1905 it was 161 per thousand of population, in 1934 it was 118 which was 0.4 above that for 1933, the lowest on record. The increasing aging of the population is shown by the proportion of the persons over the age of 70 years per 10,000 of the total. In 1911 they numbered 297 in 1921, 344, in 1931, 426 and in 1932 434. The registrar general therefore describes the increase in the number of old people as 'an outstanding feature of our vital statistics.'

The Eradication of Rabies from Great Britain

Many years ago a courageous home secretary introduced, in the face of angry opposition from dog owners, the compulsory muzzling of all dogs. As rabies could not then be passed on from animal to animal, the disease became extinct after a time. But as rabies exists on the continent of Europe it would sooner or later be introduced by imported dogs when the muzzling period was over. This was prevented by a six months period of quarantine for all imported dogs which is still in force. In the house of commons the minister for agriculture stated that five years has elapsed since the last case of rabies imported from Europe and four and three fourths from the rest of the world. He was asked whether he would reduce the period of quarantine. He would not do so, as experience had shown the six months to be necessary. Since 1919 twelve dogs imported from abroad have developed rabies while in quarantine, four of these between the fourth and the sixth month.

Escape from Wrecked Submarines

Great attention has been given by the admiralty to the problem of the escape from submarines, and a considerable advance has been made. Because of the successful use of the Davis escape apparatus, by which five men were rescued from the Poseidon in 1931, all submarines are furnished with escape apparatus, in the use of which the men of the submarine service are trained by means of a specially designed tank. A great improvement has been made on the earlier method. Each submarine is now provided with two escape chambers, which are built against the main bulkheads fore and aft and rise from the floor of the ship to the outer casing through which a hatch opens directly into the sea. The escape chambers are in the main gangway and can be brought into use by closing watertight doors, which give access to the adjacent compartments of the submarine. To ensure speed in case of emergency, all the controls of a chamber are triplicated.

In case of accident the procedure is for two men to enter the chamber wearing the Davis apparatus which is a sort of diving dress, close the water-tight doors, flood the chamber with water from the sea, and, when the water has risen far enough, open the upper hatch and by rising through it escape to the surface. The hatch is then closed and the chamber emptied by draining the water from it into the bilges. Two other men enter the chamber and the procedure is repeated.

The escape chamber system has several advantages over the one that it has replaced, not the least being a much greater speed in operation. Two men can be sent to the surface every five minutes, while those waiting to escape do not have to stand in a flooded compartment with water up to their necks. For training purposes escape chambers have been constructed at the submarine depot, Portsmouth, where men are instructed. The course of instruction is thorough and includes practice in using the escape chambers and the Davis apparatus, methods of breathing under water to avoid caisson disease, and what to do after floating to the surface from a wrecked submarine. All the men in the submarine service are to go through a course of escape training yearly as a "refresher." For this purpose the admiralty has built a training tank at Hong-Kong and another at Malta.

Kidney Complications During Gold Treatment of Tuberculosis

At the Dec 7, 1934, meeting of the Societe medicale des hopitaux, the subject of kidney complications during the gold treatment of pulmonary tuberculosis was discussed. Many tuberculosis specialists have been of the opinion that slight evidences of renal intolerance to gold salts, especially an albuminuria, ought not to be considered an indication for interrupting the treatment, because the albuminuria is only transitory and disappears spontaneously. This view is less favored at present than it was one or two years ago.

Bourgeois and his associates now report a case in which two previous series of treatments with the gold salts was accompanied by a slight albuminuria. Up to the time of beginning a third series, the patient had been given a total of 55 Gm of gold. Two days after the disappearance of the albuminuria, just as the gold treatment was begun again, the patient presented all the clinical signs of an acute nephritis, with edema of the eyelids and both feet, oliguria, fever, dyspnea, delirium, ascites and gallop rhythm of the heart. These receded rapidly following treatment. There was now no albuminuria, however, and the blood urea rose only to 43 mg per hundred cubic centimeters. Death occurred about six months later, following a severe hemoptysis. The kidneys showed the lesions of acute nephritis in the process of resolution. On chemical analysis, some of the renal tubules showed the presence of gold enclosed in the epithelium of these tubules. A total of 115 mg of gold was found in the kidneys. Bourgeois and his associates state that one ought not to continue to employ the gold salts in pulmonary tuberculosis, whenever an albuminuria occurs. In the discussion, Etienne Bernard stated that doses (total) of as high as from 60 to 80 Gm of the gold salts are tolerated without any accompanying albuminuria or rise in the blood urea. If renal complications occur, there must have existed some previous evidences of nephritis, hence one should search for these before beginning the gold treatment.

Justin-Besançon stated that, as the result of experimental study, an antidote had been found not only against acute intoxication due to the salts of gold but also to that of other toxic metals, including lead, mercury, uranium and bismuth. This antidote is sodium methyl sulphoxalate, which does not exhibit any toxic properties when injected into rabbits that have been given a lethal dose of sodium gold thiosulphate. This may prevent in the future any toxic effects of the gold salts.

Coste raised the question whether, in view of the case report of Bourgeois, one ought not to discontinue the gold treatment as soon as an albuminuria appears. One must consider the various diseases in which gold therapy is being employed.

Cases of chronic arthritis, which are usually very intolerant to the use of gold salts, rarely show any signs of nephritis even though a transitory albuminuria is observed. On the other hand, patients with pulmonary tuberculosis show evidences of nephritis from time to time, especially at the beginning of the gold treatment. One might think that polypeptide intoxication, which favors an amyloid degeneration of the kidneys, is followed by a special degree of "renal fragility." He would be far more inclined to discontinue the use of gold salts as soon as an albuminuria appeared.

In closing, Bourgeois said that the frequency of albuminuria in gold therapy is absolutely independent of the single or total dose. The renal complications should be placed in the same category as the ocular, blood and hemorrhage accidents. A search for a certain predisposition to renal complications had not thrown any light on the question. Of fifty-six cases that had shown slight evidence of renal lesions before the gold treatment had been begun, only one third had not shown renal complications. The other two thirds had shown all varieties of accidents due to the gold salts. Of eight cases of severe nephritis occurring during such therapy, four had previously shown evidences of nephritis. He would advise an estimation of the blood urea in every case before beginning the treatment.

Fatal Nephritis Following Gold Salt Injection

At the Dec. 21, 1934, meeting of the Societe medicale des hopitaux, Olmer and Sarradon reported a case in which a man, aged 37, entered the hospital with physical signs of a pulmonary tuberculosis involving the left apex and to a lesser extent of the base of the right lung. The sputum was positive for tubercle bacilli. The examination of the urine revealed nothing abnormal, especially no albumin or casts. The result of the blood urea examination, which proved to be 70 mg per hundred cubic centimeters, was not known until the day following the first treatment. A single intramuscular injection of 0.05 Gm of a gold salt was given. The following day the urine contained 9 Gm per liter of albumin, but no casts. The albuminuria rose rapidly in amount during the next few days, and the blood urea increased to 300 mg per hundred cubic centimeters. The patient died eight days after this single injection of the gold preparation, in uremic coma. No edema had ever been noted but there was a marked decrease in the urine output, only 250 cc in twenty-four hours. The blood pressure never attained a level higher than 110 systolic and 70 diastolic. The only conclusion to be drawn is that the acute toxic nephritis was due to the gold treatment in a patient who had a renal intolerance for this metal. Although such accidents are infrequent, it teaches one that a complete examination, with every known renal function test, should be made before beginning a gold salt treatment. Unfortunately, in this case, the relatively high blood urea, 70 mg per hundred cubic centimeters, was not reported from the laboratory until the day following the initial single and fatal dose.

Auric Nephritis and Amylosis

At the Dec. 21, 1934, meeting of the Societe medicale des hopitaux, Coste and associates reported the case of a man, aged 24, who entered the service of Prof. Leon Bernard with physical signs of pulmonary tuberculosis involving both lungs. Frequent examinations of the urine revealed nothing abnormal. Feb. 16, 1934, he was given 5 mg of a gold salt. The following days, gradually increasing edema of the lower extremities, marked albuminuria and recurrence of a previously existing diarrhea were noted. The latter symptom increased in severity and was accompanied by headache, stupor, anorexia and occasional emesis. The blood pressure remained constantly between 100 and 110 systolic and 50 and 65 diastolic. The heart sounds became fainter and the somnolence increased until

death, one month after the beginning of the gold salt therapy. The blood urea, from February 24 to March 3, had risen from 47 mg to 86 mg per hundred cubic centimeters. The total amount of the gold salts given was only 0.05 Gm. The necropsy revealed a large, pale liver with fatty infiltration but no amyloid changes, but in the kidneys there were extensive amyloid degenerative lesions of the glomeruli without evidences of changes indicative of an acute or chronic nephritis. The amyloid degeneration probably antedated the gold treatment, but no one can deny that the gold salt may not have precipitated acute amyloid changes, as reported by Dubrow.

Death Following Gold Treatment for Tuberculosis

At the January 18 meeting of the Societe medicale des hopitaux, Bourgeois and his associates added another fatal case following gold therapy for pulmonary tuberculosis. A man aged 34, had a nonevolutive involvement of the right upper lobe. Injections of a gold salt were begun in April 1934. An urticaria of the trunk and arms followed the first injection of 0.05 Gm, so the doses were decreased to 0.025 Gm, given once a week. The last injection was given November 2, and the total up to that date was 54 Gm of gold sodium thiosulphate. The last injection was followed by a papular eruption over the right shoulder and upper arm, as well as by a diffuse polynuritis of motor paralysis type, which increased until a complete paraplegia was noted. Lumbar puncture did not throw any light on the etiology of the Landry syndrome (ascending paralysis). The patient died, November 17, with symptoms of asphyxia of bulbar origin. No exacerbation of the pulmonary lesions accompanied the polynuritis, hence the authors feel that the gold salt alone was responsible. The urticaria following the first injection was already an evidence of intolerance to gold therapy. Such a sign has been observed by others but does not recur with the injection of gradually increasing amounts.

Health Insurance in 1933

Recent letters contained reports on the system of health insurance in vogue in Germany (THE JOURNAL, Nov. 10, 1934, p. 1463) also on the local *krankenkassen* which include the great majority of the insured (THE JOURNAL, January 26, p. 331). In the meantime the federal bureau of statistics has published further information on the year 1933.

The number of individual services rose in 1933 to almost 40,000,000 cases. About 4,000,000 more cases were treated in 1933 than in 1932. The main cause for this was the influenza epidemic of the spring of 1933. The number of cases of illness associated with incapacity for work was distinctly fewer. For each 4.5 cases there was one case with incapacity for work. The total number of such cases for the period 1929-1933 was as follows: 1929, 12,410,000; 1930, 8,653,000; 1931, 7,096,000; 1932, 5,357,000; and 1933, 6,083,000. It is evident, therefore, that the number of cases of illness with incapacity for work was in 1933 less than half that of 1929, although, by reason of the influenza, 1933 showed an increase over 1932. The average duration of the illness showed a tendency to increase: 1929, 25.8 days; 1930, 28.9 days; 1931, 29.8 days; 1932, 30.3 days; and 1933, 25.6 days. The reduction of the number of days in 1933 as against 1932 was also doubtless due to the influenza. The number of cases associated with incapacity for work was about the same in the two sexes but the illnesses of the female members were of longer duration. The number of cases in which financial aid to puerperants was granted has shown a downward trend since 1928: 1928, 810,808; 1929, 802,656; 1930, 788,391; 1931, 686,743; 1932, 599,198; and 1933, 543,330.

The federal bureau of statistics regards this fact as an indication that the economic distress rested most heavily on the strata of the population that were insured in the health insurance associations (*Krankenkassen*), the strata that, at the same time, contributed most to the preservation of the numerical status of the population. Likewise the number of death benefits has decreased from year to year: 1929, 243,108; 1930, 214,935; 1931, 200,082; 1932, 122,711; and 1933, 125,837. The increase in 1933 was only 2.4 per cent, although the total number of deaths in the German Reich increased by 4.5 per cent. This smaller increase is due to the fact that, owing to the economic crisis chiefly the older workmen in many instances have been deprived of their jobs and for that reason have gradually given up their health insurance. The total expenditure of the German *Krankenkassen* dropped from 1,217,000,000 marks (\$486,800,000) in 1932 to 1,180,900,000 marks (\$472,360,000) in 1933. The expenditures for sick benefits likewise decreased in 1933. A comparison over the five year period 1929-1933 follows: 1929, 1,740,500,000 marks; 1930, 1,523,800,000; 1931, 1,226,800,000; 1932, 857,900,000; and 1933, 835,400,000. Sick benefits provide for the treatment of patients by licensed physicians, dental treatment, medicines, hospital care, domiciliary care, house money, cash allowances, pocket money and financial aid for convalescents. The cash allowances ranged as follows: 1929, 684,000,000 marks; 1930, 509,000,000; 1931, 369,000,000; 1932, 220,000,000; and 1933, 201,000,000. The expenditures for cash allowances to patients have thus dropped since 1929 to less than one third. The same trend may be observed in the expenditures for medicines and for hospital care. Thus the expenditures for medicines dropped from 237,800,000 marks in 1929 to 113,000,000 in 1933 and the expenditures for hospital care declined from 274,000,000 marks in 1929 to 176,000,000 in 1933. A similar decline was noted in the expenditures for medical care: 1929, 410,000,000 marks; 1930, 393,000,000; 1931, 328,000,000; 1932, 258,000,000; and 1933, 251,000,000. The administrative expenditures dropped from 130,000,000 marks in 1929 to 111,000,000 in 1933. The cost per member was 6.21 marks in 1929 and 6.13 marks in 1933. The receipts decreased even more than the expenditures. The receipts of the entire body of *Krankenkassen* (except the *Ersatzkassen*) amounted in 1929 to 2,109,000,000 marks; 1930, 1,922,000,000; 1931, 1,429,000,000; 1932, 1,078,000,000; and 1933, 1,031,000,000. The receipts thus fell off since 1929 by more than 1,000,000,000 marks. The dues per member were 97.90 marks in 1929 and 59.52 marks in 1933. In 1933 the highest receipts per member were reported by the marine *Krankenkasse* (102.72 marks) and the miners *Krankenkassen* (94.27 marks). The lowest receipts were found in the rural *Krankenkassen* (40.43 marks), which for a number of years have had the most difficult status of all the *Krankenkassen*. The property holdings or net worth of the *Krankenkassen* amounted in 1933 to more than 800,000,000 marks; the reserve funds increased from 408,300,000 marks to 436,400,000 marks. The reserve funds amount now to 30 per cent of the average annual expenditures during the previous three years (the minimal legal reserve is 25 per cent of the average expenditures of the previous three years).

The Saliva and Immunity to Diphtheria

The explanation given by Behring a number of years ago for diphtheria immunity (presence of a sufficiently large amount of antitoxin in the blood) does not hold good as Professor Dold, hygienist of Tübingen, has pointed out in face of the fact that there are animals which, in spite of marked parenteral (subepithelial) sensitiveness to diphtheria bacilli and their poison and in spite of the absence of demonstrable quantities of diphtheria antitoxin in the blood, do not spontaneously contract pharyngeal or nasal diphtheria nor can they be made

to develop diphtheria by a massive experimental infection of the pharyngeal and nasal mucous membranes with virulent and toxic diphtheria bacilli. It is evident, therefore, that in these cases other protective mechanisms must be present. Of these, the protective action of the saliva and of the nasal secretion is doubtless the most important. Likewise the saliva of human beings (of adults and of the older school children) possesses such protective mechanisms capable of combating toxic diphtheria bacilli. It may serve to check their development, it may kill them after they have developed or (in the event of long continued action) it may transform them into diphtheroids or into pseudo diphtheria bacilli, whereas the diphtheria toxin is not made inactive by human saliva. In establishing immunity to diphtheria and in connection with its origin and spread, this action of the saliva (presence or absence of these protective mechanisms) must be at least of equal importance with the antitoxin content of the blood. For, ahead of the antitoxic immunity of the blood, which constitutes, as it were, the second and last reserve force, the first line of defense is formed by the saliva or the nasal secretion, with the described antibacterial protective mechanisms. The therapeutic value of the antitoxin serum is, of course, in no wise affected by these observations.

Back-to-Nature Nutrition and Protein Metabolism

The subject of back-to-nature nutrition and protein metabolism was recently discussed by Professor Bickel before the Berlin Medical Society. In view of the tendency manifest in Germany to practice nature cures and to introduce the tenets of popular medicine into every possible field, a discussion of this kind was at this time peculiarly opportune. In primitive and civilized man, Bickel pointed out, a mixed form of nutrition such as corresponds to the nature of man, has always been in the foreground. A one-sided nutrition, when found, is nearly always dependent on external influences or, in other words, is forced. An exclusive diet of raw foods cannot be regarded as a natural diet. For optimal nutrition, vegetable protein must always be supplemented by animal protein. In the experiments of Hindhede, with a limited nitrogen intake the nitrogen balance is preserved only by compensatory limitation of all combustion processes. Thereby the C/N quotient is abnormally increased and the quality of all oxidation processes is reduced. Bickel designated this as "dysoxidative carbonuria." It appears even when the nitrogen balance is still positive and it increases when the nitrogen balance drops to the negative side. An increase of protein leaves the quotient normal and uninfluenced, hence natural nutrition does not require a strict limitation of the protein intake. Not all forms of protein are of equal value. The low and the average values are assignable to the vegetable proteins, and the high values to the animal proteins. If human beings or animals are nourished with proteins having only average or low values, such nutrition may be designated as of low quality, and the increase of body weight will be inadequate, there will be a defective resistance to infections, the nitrogen balance will be negative, and dysoxidative carbonuria will appear. If one feeds, for example lentil protein, combined with amino-acids, an increase of the carbonuria will be brought about, even though large quantities of amino acids are added to the diet. Addition of amino acids to a mixed diet that is in itself adequate or substitution of amino-acids for a portion of the nutritional protein, likewise leads generally to carbonuria.

The Health Record Book

In response to a request of the Amt für Volksgesundheit of the national-socialist party, a health record book comprising sanitary blanks for three periods of life has been issued, namely, for the period of infancy and the preschool age for

the period of growth, from ages 6 to 18, and for the adult period from ages 19 to 65. The tasks of the Amt für Volksgesundheit lie chiefly in the field of health service, health education and health leadership and constitute a supplementation of the measures of the central government, which deal mainly with health building and health preservation. The Amt für Volksgesundheit intervenes more promptly, long before the central government can get into action. It acts also in those cases in which the functions of the health insurance system and the state have become exhausted. Its goal is to reach every person and to improve the health and the working capacity of every one, so far as possible, within the limits of his hereditary biologic and racial aptitudes. For that purpose it is necessary to observe a person in association with his family. Hence the examination of the family must be more emphasized, and the old type of house physician must again be cultivated.

Merger of German Neurologic Societies

The Gesellschaft Deutscher Nervenärzte and the Deutscher Verein der Psychiatrie have merged under the title "Gesellschaft Deutscher Neurologen und Psychiater," although each of the two resulting departments will retain a certain measure of independence. The psychiatric department will absorb also the Deutscher Verband für psychische Hygiene und Rassenhygiene. Professor Rüdin of Munich has been appointed "federal director."

ITALY

(From Our Regular Correspondent)

Jan 31, 1935

Congress of Occupational Medicine

The eleventh Congresso nazionale di medicina del lavoro was held recently in Turin. The first paper on the program, dealing with "Work on the Sea," was presented by Prof. Nicolo Castellino, occupant of the chair of occupational medicine (medicina del lavoro) at the University of Naples. He considered the diet of seamen, pointing out the present deficiencies and suggesting dietary tables calling for a greater consumption of protein substances and a diminution of carbohydrates, which are now used in excess. The author stressed the frequency of venereal diseases among seamen and proposed the adoption of prophylactic measures similar to those used in the army. The two disorders especially common in seamen are rheumatism and cardiovascular disturbances. Although rheumatism is caused by the nature of the surroundings in which the men are employed, in evaluating the relations between the organism and the disease it is necessary to take account also of the individual factor, for it is evident that every one has the type of rheumatism for which his organic peculiarities prepare the way. To explain the origin of cardiovascular diseases, the speaker stated that it is necessary to take account of the rapid changes in the weather and in the atmospheric pressure, of the fatigue poisons, and of the action that excessive perspiration exerts on the walls of the blood vessels. As seamen live in an atmosphere saturated with chlorides and iodine vapors, they commonly present physiologic hyperthyroidism. This observation should lead to the application of an energetic prophylaxis and to a more careful selection of men suitable to the calling. Diseases of the respiratory apparatus are next in order among those that attack seamen. In their causation humidity and fog are important causative factors, as they may constitute the vehicle of infectious microorganisms and harmful vapors. Congestive diseases of the pulmonary tree predominate, whereas tuberculous disorders are rare.

Professor Quarelli spoke on the subject "Work on the Sea and on Fresh Water Bodies," considering especially the dis-

eases of fishermen. These may arise (1) from the excessive or the peculiar nature of the work, (2) from the environment, or (3) from the postures, compressions and motions involved in the work. Among the disorders referable to postures and to working positions, importance attaches to the erect or to the sitting posture that the fisherman must constantly assume in certain fishing places. Varices of the leg are frequent, also a certain amount of deviation and deformation of the dorsal portion of the spinal column in rowers and in those whose duty it is to draw in the nets to the shore. Among the disorders of compression may be mentioned the marked hollowing out of the right subclavicular fossa in boatmen, dyskinesia and cramps. Among the types of disease due to the environment, the speaker mentioned certain endemico-infectious disorders, those ascribable to the necessity of living exclusively on the fruits of fishing in some localities, scabious or purulent dermatosis, injuries due to inoculations of poison by fish and *Coelentera*, and malaria among those who work in localities in which mophelism is endemic.

Professor Micheli, senator, director of the Clinica medica in Turin, took as his subject "Exogenic Superinfection in Relation to the Question of Occupational Tuberculosis." The question has been in the foreground for several years but is still unsettled, being connected, on the one hand, with the question as to whether or not pulmonary tuberculosis that develops in persons employed in the aid of tuberculous patients may be regarded as an occupational disease, and, on the other hand, with subjects of scientific and practical interest, such as phthisiogenesis and prophylaxis. The author shares the opinions of the school that holds that so-called tuberculosis of adults has an endogenic origin. He is led to this conception by arguments of various nature, as the frequency of bacillæmia, and the presence of live and vital germs in the tracheobronchial glands even when they are calcified, from which the germs themselves easily enter the blood stream. Modern theories on immunity affirm that, while the organism may be capable of overcoming readily the first tuberculous infection, it does not succeed in destroying the germs that the infection brought into the organism, for such germs remain alive even in the cicatricial processes of calcification. "Early infiltration," according to the speaker, is the expression of the exacerbation of small preexisting foci, surrounded by an area of exudative inflammation.

Professor Ranalletti of Rome spoke on poisoning due to carbon disulphide, pointing out that in such cases the principal morbid manifestations concern the nervous system. These present themselves in the form of a psychosis of a maniacal, confusional or demential type, polyneuritis that involves all four limbs. The localizations of polyneuritis may affect also the nerves and the flexor muscles. This is an important characteristic for the differential diagnosis as against pleuritis of a different nature.

Dr. Ando Gianotti considered the neurovegetative and endocrine changes that are observed in poisoning due to carbon disulphide, with especial reference to the adrenal capsules. He concluded that under such conditions there are a special state of lability of the parasympathetic system and evident endocrine changes that affect particularly the genitalia, the islands of Langerhans, and the adrenal cortex.

Dr. Di Donna spoke on the hygienic prevention of sulphur-carbonism, a question that is today important owing to the wide industrial use of carbon disulphide. Prophylaxis may be accomplished either by preventing the gas from spreading into the work rooms or by having the workmen put on gas masks and protective garments.

As the last official speaker, Professor Guglianetti described the injuries that result to the eye through overuse and constitute eye strain. One of the most typical occupational dis-

cases is the myasthenia of miners. Among the diseases due to the environment of the workman may be mentioned those produced by defective light or by radiations, such as cataract in men working near hot fires and in glass blowers and the eye lesions due to roentgen rays. Also in association with crisson disease there are eye changes, and disorders of the visual apparatus may be due to the direct action of gas, vapors or dust contained in the air of the workman's environment or to the action of war gases.

Holsten spoke on the intoxication states due to mercury, which are observed in some hat factories. Vigham referred to disturbances in workmen who apply spray varnishes to automobile bodies, pointing out that the digestive apparatus is most commonly affected, together with liver involvement. The changes in the blood were the least marked.

Naples was chosen as the meeting place for the next congress. The following subjects will be discussed: (1) pathology and hygiene of noises; (2) insurance against occupational diseases after three years' trial, and (3) occupational poisonings due to the use of new chemical products.

Results of the Operation for Gallstones

At one of the recent sessions of the Vienna Medical Society, Prof. Dr. Finsterer discussed the results of the operation for gallstones. In order to judge correctly the results secured, not only the immediate results of the operation but also the permanent results must be considered. The early operation (under age 40), as recommended by Enderlén and Hotz, is still rejected by many internists, which Professor Finsterer regards as an error, for the mortality of the interval operation, and also of the early operation in an acute attack, associated with fever, in patients under 40 years of age, is lower than in patients from 50 to 60 years old. Finsterer reported that in his own series of cases he had only two deaths in 136 interval operations, and no deaths in thirty-nine cholecystectomies performed in the acute stage in patients under 40. The speaker stated, however, that in the interval operation the age of the patient, in his opinion is not important. In thirty-nine patients whose ages ranged from 60 to 79 he had but one death. In his own series of cases the age was of slight importance in the acute stage. In the 40-50 age group all his twenty-nine cases ended in recovery; in the 50-60 age group the mortality was 9 per cent in thirty-one cases, but in the 60-70 age group only 5 per cent in a series of nineteen patients, in seven patients more than 70 years old, with gangrene of the gallbladder, the mortality rose to 28 per cent. The early operation in an acute febrile attack (within forty-eight hours after the beginning of the attack) gave good results (forty-six cases with 2 per cent mortality), whereas the late operation in a series of seventy-nine cases gave more than 6 per cent mortality. Hence the early operation is safer than a waiting policy. It may be observed that cholecystectomy gives better results than cholecystostomy (118 cases with three deaths as against seven cases with three deaths). These figures agree closely with the experiences of many other operators. But if the patients are not brought to the physician until necrosis of the pancreas or perforation peritonitis has developed, the operation is to be sure, still indicated, but the results are then poor (sixteen deaths in eighteen cases). In stone of the choledochus the prognosis depends on the degree and the duration of the obstruction but also on the operation. The results are excellent in simultaneous cholecystectomy and supraduodenal choledochoduodenostomy (seventy cases with 7 per cent mortality) particularly in elderly persons (twenty cases with 5 per cent mortality). Aged patients, more than 70 years old, reacted surprisingly well,

all six cases ending in recovery. The results of choledochus suture are not so good (eleven cases with one death), and very bad in hepatic drainage (eighteen cases with more than 22 per cent mortality). It is important that the anastomosis be planned on generous lines, in order that, immediately after the operation, all the bile may again enter the intestine. Finsterer designates as an acute attack only the febrile attack with a temperature of at least 38 C (100.4 F). In such cases, because of the possibility of a later complication, it is better not to delay the operation long. For the intervention he does not use general (ether) anesthesia but only paravertebral or splanchnic anesthesia. To this fact he ascribes his good results in aged patients. The total elimination of ether does away with postoperative pneumonia and the damage to the liver. In his own series of ninety-three cases in which the patients were more than 60 years of age, pneumonia was entirely absent.

The permanent results were remarkably good in cholecystectomy in the acute febrile stage, for, of seventy cases in which the operation dates back from three to twenty years, 91 per cent (sixty-four patients) are free from symptoms. In this series four patients have a slight hyperacidity, and only two patients complain again of symptoms. In one case in a supplementary operation no stones but a cholangitis was found. A second patient had a duodenal ulcer. A recent gastric resection brought permanent freedom from pain (sixteen years after the original operation). In the interval operation the results are not so good, for of 178 patients only 142 are free from pain (80 per cent). Twelve patients have at times slight symptoms but have regained their complete working capacity. Twenty-four patients, however, have at times rather severe symptoms, but in only two cases is the pain ascribable to cholangitis; in the other cases various causes are responsible (ulcer, colitis). In chronic cholangitis without stones the results are poor (of thirty-four patients only 66 per cent were cured, while in 17 per cent no cure was effected). In stone of the choledochus the permanent results after hepatic drainage or suture of the choledochus are not satisfactory (of thirteen patients only five recovered, while three died). On the other hand, the permanent results of choledochoduodenostomy were very good (of forty-two patients, thirty-seven, or 88 per cent, have been well for periods ranging from three to twelve years; three have slight symptoms, and only two remained uncured). The charge that this operation incurs a danger of an ascending infection is unfounded. Finsterer presented several patients who had undergone this intervention with success. The precondition of a permanent result is that the anastomosis shall remain wide open; hence a longitudinal incision along the choledochus and likewise along the duodenum must be made. The bad results are due, in 50 per cent of the cases, to a duodenal ulcer, whereas cholangitis is present in only about 25 per cent of all cases, or 4 per cent of the operations. A comparison with the sparse statistics on cases treated by internists reveals that, even with institution of a strict diet, in only 40 to 50 per cent was a reasonably permanent freedom from symptoms effected, and that from 16 to 25 per cent died without operation from their gallstone disease, or, because of a dangerous complication, were operated on a second time, whereas in the operations including all complications, a mortality of from 45 to 65 per cent was recorded. In 87 per cent, however, complete recovery, extending in some cases over a period of twenty years, was secured. The other cases showed a 4 per cent incidence of persistent cholangitis. The remaining patients suffered from a duodenal ulcer, colitis, renal stone and the like. The results of operation are thus much better than those of internal treatment, but with the cooperation of the internist they might be still better if the value of the early operation in the younger years and also the value of the early operation in the acute febrile stage become more generally recognized, and if the

surgeon during the intervention even in the presence of stone, will look carefully for concomitant disorders particularly duodenal ulcer, and will treat also these operatively

During the discussion following the presentation of the paper, it was apparent that a large majority of the surgeons agreed, to a great extent with the statements of the speaker Prof Dr Ewald remarked that the question of early operation in gall-stone disease reminded him of a similar discussion, thirty-five years ago, on the problem of early operation in appendicitis This question, also, was answered in favor of the radical point of view Professor Moszkowicz uttered an interesting warning against a surgical intervention immediately after a roentgen examination The agents used in connection with a roentgen examination are not indifferent to the organism hence from six to eight days should intervene between a roentgen examination and an operation

Suicide Statistics for 1934

A compilation of the suicides for 1934 (including unsuccessful attempts) has just been published and gives a good insight into conditions in Vienna in recent years From these statistics it appears that since 1930 the number of persons weary of life's struggle has been decreasing Whereas in 1930 the number was 3,065 and in 1933 still 2,825, it dropped last year to 2,507, 1,219 men and 1,288 women The number of successful attempts was 1,019 (592 men and 427 women) Nearly all age groups were represented from a 10-year-old boy to an 83-year-old woman The most important causes for the attempt were economic distress and unemployment 413 cases family quarrels 366, sickness 344 mental disturbance, 182 unfavorable physical conditions 169 unhappy love affairs 165 fear of punishment 67, and grief over the death of near relatives or friends 51 The cause remained unexplained in 745 cases Both sexes showed a predilection for poison considerably more than half of the suicides were accomplished by means of illuminating gas (544) 225 preferred death by hanging, 98 used firearms 78 persons sought death by leaping from great heights, 52 by drowning, 9 by the use of a chopping or cutting weapon, 12 persons voluntarily allowed themselves to be run over, and one man chose a death by burning It is interesting to note that in the winter months the number of suicides (498) was distinctly fewer than in summer (521) In the months of March, April and May, more than 100 suicides were recorded in September and December only 70 each The number of attempted suicides among the women was much greater than among the men

Marriages

ROBERT PARK JR. Beaver Falls, Pa. to Miss Marjorie Lee Sprye of High Point N. C., in Brooklyn, February 16

ANGUS C. MEAGHER Toppensish, Wash. to Miss Glenna Lee Pratt of Yakima at Butte, Mont., Dec. 29, 1934

HENRY SHIRLEY MILLETT, Brooklyn to Miss Annie Ostrom Alexander of New York February 11

HOMER A. WHITTINGTON, Natchez, Miss., to Miss Elizabeth Wood of Brookhaven, February 5

PAUL A. BREHM, Milwaukee, to Miss Mary Elizabeth Harrison of New York, January 21

SIGMOND I. SHAPIRO Warren Ohio, to Miss Ruth E. Leopold of Youngstown, March 13

HERBERT S. RAINES to Miss Margaret P. Swartz, both of Philadelphia, March 4

ALEXANDER L. STEARNS to Miss Elizabeth J. Day, both of Chicago, March 24

AMERICO FERLITA to Miss Nina Tagliarini both of Tampa, Fla., February 28

KELLIE N. JOSEPH, Decatur, Ala., to Miss Dell Ivie of Alto, Ga. March 23

Deaths

Edgar Moore Green of Easton, Pa., University of Pennsylvania Department of Medicine, Philadelphia 1886 past president of the Northampton County Medical Society, fellow of the American College of Physicians formerly member of the state board of medical education and licensure at one time member and president of the board of education internist on the consulting staff of St. Luke's Hospital Bethlehem life member of the board of trustees of Lafayette College, aged 72 died, March 9, of arteriosclerosis

Thomas Cook Stellwagen of Philadelphia, Jefferson Medical College of Philadelphia, 1903, professor of genito-urinary surgery at his alma mater, member of the American Urological Association, member and past president of the American Association of Genito-Urinary Surgeons served during the World War aged 55 at various times on the staffs of the Philadelphia General Hospital St. Joseph's Hospital, Jewish Hospital and the Jefferson Hospital where he died, March 15 of angina pectoris

Mary Gage Day of Kingston, N. Y., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1888, member of the Associated Anesthetists of the United States and Canada on the staff of the Benedictine Hospital on the staff and member of the board of managers of the Ulster County Tuberculosis Hospital and member of the courtesy staff of the Kingston City Hospital, aged 77, died, March 7 in St. Peter's burg Fla. of injuries received in an automobile accident

Harold Gould Garwood, Denver Johns Hopkins University School of Medicine Baltimore 1904 fellow of the American College of Surgeons served during the World War formerly instructor in surgery, University of Colorado School of Medicine at various times on the staffs of the Colorado General Denver General St. Luke's and Children's hospitals aged 59 died March 8 in the Station Hospital United States Army Fort Sill Okla., of lobar pneumonia

Colman Ward Cutler of New York College of Physicians and Surgeons, Medical Department of Columbia College New York 1889, member of the board of directors of the National Society for the Prevention of Blindness aged 72 at various times on the staffs of the New York Hospital Woman's Hospital St. Mary's Hospital for Children and St. Luke's Hospital where he died March 17, of arteriosclerotic heart disease and cerebral hemorrhage

Thomas McKean Thompson McKennan of Pittsburgh, University of Pennsylvania Department of Medicine, Philadelphia 1882 professor of neurology University of Pittsburgh School of Medicine member of the American Neurological Association and the Association for Research in Nervous and Mental Disease aged 75 neurologist to St. Francis Hospital, where he died February 16 of lobar pneumonia

William Eggleston, Hartselle, S. C., University of Nashville (Tenn.) Medical Department, 1898 member and president of the South Carolina Medical Association, past president and secretary of the Darlington County Medical Society, chairman of the South Carolina State Board of Health served during the World War, aged 61, died, March 24, of cerebral thrombosis

Henry William Kice of Dover N. J. University of the City of New York Medical Department 1888 at one time secretary of the Union County Medical Society formerly mayor, member of the board of health and board of education and medical inspector of the public schools of Wharton aged 74 died, March 6, of arteriosclerosis and carcinoma of the prostate

Joseph Taylor Griest, St. Louis Barnes Medical College, St. Louis, 1909 member of the Missouri State Medical Association formerly professor of chemistry and toxicology at his alma mater and professor of toxicology and clinical medicine, National University of Arts and Sciences Medical Department, aged 55, died, March 2, of bronchopneumonia

Charles Fletcher Milligan of Clayton, N. M. University Medical College of Kansas City, 1906 president of the New Mexico Medical Society, secretary and past president of the Union County Medical Society on the staff of St. Joseph Hospital aged 55 died suddenly February 2 of epidemic (lethargic) encephalitis

Theodore Engelbach of Grand Isle, La. Tulane University of Louisiana Medical Department, New Orleans, 1894, also a pharmacist acting assistant surgeon U. S. Public Health Service, deputy coroner and justice of the peace aged 78 died, February 26, of acute pyelonephritis and bilateral bronchopneumonia

John Martin Birkner, Lincoln, Neb. Missouri Medical College, St. Louis, 1886, at one time professor of military surgery and clinical surgery, Nebraska College of Medicine served during the World War on the staff of St. Elizabeths Hospital, aged 78, died, February 24, in a local hospital of hypostatic pneumonia.

Louis W. Dean, Utica, N. Y. New York Homeopathic Medical College and Hospital, 1890, fellow of the American College of Surgeons, formerly on the staffs of the Utica General and Utica Homeopathic hospitals, aged 76, died suddenly, March 2 in Charlottesville, Va., of heart disease and arteriosclerosis.

Jacob F. Hultgen & Chicago Northwestern University Medical School Chicago, 1900 formerly professor of clinical medicine, Lovola University School of Medicine, veteran of the Spanish-American War, on the staff of the Evangelical Hospital, aged 62, died March 12, of carcinoma of the prostate.

John Garrett Wilson, Perth Amboy, N. J. University of Pennsylvania Department of Medicine Philadelphia 1876 member of the Medical Society of New Jersey for many years on the staff of the Perth Amboy General Hospital, aged 82, died, March 9, of arteriosclerosis and pulmonary edema.

Hugo Christian Herman Schroeder & Granite City, Ill. Hahnemann Medical College and Hospital, Chicago 1909 past president of the Madison County Medical Society on the staff of St. Elizabeths Hospital, aged 49, died February 25, in the De Paul Hospital, St. Louis, of heart disease.

Millard Winfield Baysinger, Chicago Missouri Medical College, St. Louis, 1883 University of the City of New York Medical Department, 1891, aged 77, died, February 24, of hypertension chronic nephritis and uremia.

Charles Haddon Spurgeon, Terre Haute Ind. Indiana University School of Medicine, Indianapolis, 1923, member of the Indiana State Medical Association, on the staff of the Union Hospital, aged 54, died, February 22, of coronary thrombosis.

Arthur Aratoon Basil, Johnstown, Pa. Jefferson Medical College of Philadelphia 1908, member of the Medical Society of the State of Pennsylvania, served during the World War, aged 54, died, February 25, of arteriosclerosis and chronic nephritis.

Cephas C. Greiner, Pemberville Ohio Chicago Homeopathic Medical College, 1896 member of the Ohio State Medical Association, aged 71, died February 23, in the Community Hospital, Fremont, of injuries received in an automobile accident.

John Love Davis, Watertown, Tenn. Vanderbilt University School of Medicine, Nashville, 1893, member of the Tennessee State Medical Association for many years health officer of Watertown, aged 69, died, February 22, of cerebral sclerosis.

Frank M. McClelland, Franklin Pa., Western Reserve University Medical Department Cleveland 1887 member of the Medical Society of the State of Pennsylvania, aged 75, died February 4, at his home in Utica of heart disease.

Harvey S. Smith & East St. Louis Ill. Marion Sims College of Medicine, St. Louis, 1899, past president of St. Clair County Medical Society, formerly member of the board of education, aged 60, died, February 13, of heart disease.

Victor Lyall Goodwill, Charlottetown P. E. I., Canada Queen's University Faculty of Medicine, Kingston Ont. 1899, member of the American Psychiatric Association, aged 60, died, February 26, of coronary thrombosis.

Malcolm Lamson McInnes, Toledo Ohio Loyola University School of Medicine Chicago, 1931, aged 32 on the staffs of the Flower Hospital and the Mercy Hospital, where he died, January 27, of tuberculosis.

Edward A. Stierberger & Union Mo. Marion-Sims College of Medicine, St. Louis, 1897 president and formerly secretary of the Franklin County Medical Society, aged 59, died, February 20 of heart disease.

Arthur McKendree Frost, Mount Vernon, Ill. Physio-Medical College of Indiana Indianapolis, 1888, aged 74, died, February 1, in the Anna (Ill.) State Hospital, as the result of a cerebral hemorrhage.

Joseph Croshor Boggs, Pittsburgh, Western Pennsylvania Medical College, Pittsburgh, 1890 served during the World War, aged 67, died, February 21, in San Antonio, Texas, of coronary occlusion.

Eleanor Alice Tebeau, Howard, R. I. Tufts College Medical School Boston, 1932, assistant physician to the State Infirmary, aged 29, died, Dec. 20 1934, in Cranston, of intestinal obstruction.

Myron H. Williams, Mango, Fla., Medical College of Ohio, Cincinnati, 1879, aged 80, died, February 24, in the Methodist Hospital, Indianapolis, of prostatic hypertrophy and arteriosclerosis.

Louis Valmore Masse, Warren, Ont., Canada, School of Medicine and Surgery of Montreal, Faculty of Medicine of the University of Laval at Montreal, 1894, aged 61, died, January 25, of pleurisy.

George Andrew Stock, Outwood, Ky., Jefferson Medical College of Philadelphia, 1898, on the staff of the Veterans' Administration Facility, aged 58, died, February 2, of uremia and nephritis.

Edmund Felix Taake, Seattle, St. Louis University School of Medicine 1905, member of the Washington State Medical Association, aged 59, died, February 8, of carcinoma of the pancreas.

Ira E. Parker, Dryden Mich., Detroit College of Medicine, 1885 member of the Michigan State Medical Society, aged 74, died suddenly, in February, at St. Petersburg, Fla., of heart disease.

Leslie Montague Winn, Fulton, N. Y. College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1891, aged 67, died, March 4, of cerebral hemorrhage.

William S. Gregory, St. Joseph, Mo. Northwestern Medical College, St. Joseph, 1893 Central Medical College of St. Joseph, 1896, aged 85, died, January 29, of prostatectomy.

John Milton Sims, Macedonia, Ill., St. Louis College of Physicians and Surgeons, 1895, member of the Illinois State Medical Society, aged 75, died, March 2, of heart disease.

Agnes Virginia Fuller, Chicago, Hahnemann Medical College and Hospital, Chicago, 1902, aged 72, died suddenly, March 7, of cerebral hemorrhage and diabetes mellitus.

Henry William Clausen, St. Louis, Barnes Medical College, St. Louis, 1894, aged 72, died, February 22, in the Firmin Desloge Hospital, of adenocarcinoma of the rectum.

John C. Derbofen & New Orleans Tulane University of Louisiana Medical Department, New Orleans, 1899, aged 63, died January 11, of influenza and heart disease.

Edmond Alfred Genereux, New York, Harvard University Medical School, Boston, 1915 served during the World War, aged 46, died, March 3, of heart disease.

Temple K. Brown, Portland, Mich., Detroit College of Medicine, 1907, aged 55, died, February 26, in St. Lawrence Hospital, Lansing, of rupture of the pancreas.

Robert Lee Boyd & Russellville, Ky. University of Louisville Medical Department, 1890, aged 70, died, February 26, of diabetes mellitus and cerebral hemorrhage.

Perryman F. Page Jr., Taft, Calif., Vanderbilt University School of Medicine, Nashville, Tenn., 1909, aged 55, died, January 14 in Bakersfield, of acute myelitis.

Isaac Walter Hodgins, Pottsville, Pa., Jefferson Medical College of Philadelphia, 1894, aged 64, was found dead in his office, March 8, of heart disease.

J. W. Weber, Lewisville, Ohio Starling Medical College, Columbus, 1882, formerly county health officer, aged 75, died, March 9, of coronary occlusion.

Stephen Francis Donovan, Derby, Conn., College of Physicians and Surgeons, Baltimore, 1902, aged 55, died, February 21, of heart disease.

Truitt H. Nelson, Alamo, Ga., University of the South Medical Department, Seawee, Tenn., 1906, aged 52, died, February 3, of heart disease.

Dominic John Gardetto, Milwaukee, Marquette University School of Medicine, Milwaukee, 1921, aged 39, died, March 5, of injuries received in a fall.

Harry Jackson Knapp, Perryville, Mo., St. Louis College of Physicians and Surgeons, 1901, aged 68, died recently, of carcinoma of the stomach.

Charles R. Davis, Baltimore, University of Maryland School of Medicine, Baltimore, 1890, aged 76, died, January 16, of chronic nephritis.

W. J. Walker, Tiptonville, Tenn. (licensed in Tennessee in 1889) aged 71, died, Dec. 17, 1934, in Dyersburg, of heart disease.

John H. Durham, Durant, Okla., Hospital College of Medicine, Louisville, Ky., 1898, aged 62, died recently, of pneumonia.

William R. Edwards, Roscoe, Ga., Southern Medical College, Atlanta 1891, aged 74, died, March 4, of pneumonia.

Richard L. Falley, Bible Grove, Ill., St. Paul Medical College 1886, aged 75, died, February 26, of heart disease.

Correspondence

COD LIVER OIL

To the Editor—I have just read the editorials in THE JOURNAL, March 16 and 23, entitled "Cod Liver Oil" (p 926) and "Variations in Behavior of Vitamin D" (p 1008). Each of these articles makes prominent reference to the recent publication from this laboratory, in which a physiologic difference between the vitamin D of cod liver oil and the vitamin D of bluefin tuna liver oil was demonstrated. Unfortunately, there is an error in each of these editorial interpretations, to which attention should be called.

The first editorial states that "perhaps the most striking support for the peculiar efficacy of cod liver oil has been recently brought forward by Bills, Massengale and Imboden, who found that blue fin tuna liver oil with 40 000 units of vitamin D per gram was only one sixth as effective when assayed with chicks as was cod liver oil with only 100 units of vitamin D per gram." The second editorial, in discussing the viosterol-cod liver oil anomaly, says "A still more striking instance of discrepancy between these two widely used sources of the antirachitic factor has been cited by Bills, Massengale and Imboden. They compared cod liver oil with about 100 units per gram with blue fin tuna liver oil with 40 000 units per gram (both oils assayed with rats) on the basis of the behavior in chicks, the blue fin tuna oil was only a sixth as effective as was the cod liver oil."

The wrong impression which a reader of these editorials would get is that a given quantity of bluefin tuna liver oil, despite its relatively enormous potency when assayed with rats, is but one-sixth as effective for chicks as is the same quantity of cod liver oil. Our published work states most explicitly (and repeatedly) that the comparison was made on a 'rat unit for rat unit' basis. Thus, while it is true that one rat unit of bluefin tuna liver oil is only about one-sixth as effective for chickens as is one rat unit of cod liver oil, it is also true that one gram or one drop of bluefin tuna liver oil is many times more effective for chickens than is one gram or one drop of cod liver oil, the reason for this being that the former contains a vastly greater unitage per gram than the latter. Applying the necessary arithmetic, one finds that the bluefin tuna liver oil, which is 400 times as potent as cod liver oil in vitamin D for the rat, is one sixth of 400, or $66\frac{2}{3}$ times, as potent, gram for gram, for the chicken.

It is no simple matter to keep one's thoughts straight when considering the distinctions between the several forms of vitamin D. One is never justified in saying that one form is more, or less, potent than another, unless one makes the species comparison clear. For instance, in the present case, if the species employed for standardization of the oils had been the chicken, and the species for comparison had been the rat, it would have resulted that, chicken unit for chicken unit, bluefin tuna liver oil is six times more effective than cod liver oil for the rat. The same argument, of course, applies to comparisons of viosterol and cod liver oil, in which the species difference is even greater than between the two fish oils.

It may not be amiss to emphasize at this point what I have already indicated in my recent monograph in *Physiological Reviews*—namely, that the human infant resembles the rat much more closely than it resembles the chicken as regards its response to different kinds of vitamin D. If the reverse were true, the chicken rather than the rat would be the animal of choice in making assays of such products as viosterol and bluefin tuna liver oil when these agents were intended for human medication.

A second, minor error appears in the editorial of March 23 in which the first sentence in which our paper is mentioned leads the reader to think that our present work is "a still more striking instance of the discrepancy between these two widely used sources of the antirachitic factor" (referring to cod liver oil and viosterol). If our work is a striking instance of anything, it is of the multiple nature of vitamin D, but surely the present paper had nothing to do with viosterol.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

USE OF TETANUS ANTITOXIN

To the Editor—I am anxious to find out: 1. What is the difference in the value of the intravenous and intraspinal injections of tetanus antitoxin? 2. If it is injected into the spinal canal will it not quicker neutralize the toxins attached to the nerve cells than in the intravenous route? 3. Are not the toxins liberated by the tetanus bacillus carried to the nerve cells of the cord almost wholly by the lymphatic system and not by the blood stream? 4. Is it considered that there is much more danger to the patient by intraspinal than by intravenous injections and is it common to have a temperature of from 105 to 107 follow intraspinal injections of from 20 000 to 30 000 units? 5. When the antitoxin is injected into the canal how is it taken up in the cord in order to neutralize the toxins attached to the nerve cells? 6. How much antitoxin in a tetanus patient should one usually inject? How often repeat and for what number of days? 7. If a desensitizing dose should give the patient a reaction in an active case of tetanus how should one proceed? If you are unable to answer all these questions for me could you give me any information where I can get the latest writings on tetanus or the addresses of any medical men who have written recent papers on this subject?

M. D. Illinois

ANSWER—1 and 2. It is not known whether the intravenous or the intraspinal injection of tetanus antitoxin is the more effective or whether the antitoxin reaches the affected nerve cells if at all, sooner if it is injected intraspinally. Indeed, there is grave doubt whether the antitoxin can neutralize the toxin after it has united with the nerve cell.

3. It has been thought that tetanus toxin does not reach the nerve cells by way of the blood but by way of the axis cylinder of motor nerves. Recently Abel (*Science* 79 63 [Jan. 26], 121 [Feb. 9] 1934), from reexamination of the evidence and from the results of his own investigations, has concluded that tetanus toxin reaches the central nervous system only by way of the arterial blood. It would be difficult to explain how the toxin could reach the nerve centers from the peripheral parts of the body by the way of the lymphatic system.

4. The intraspinal injection of appropriate amounts of antitoxin is not regarded as more dangerous to the patient than the intravenous injection. The amount of the intraspinal injection is governed by the amount of cerebrospinal fluid withdrawn beforehand. The number of antitoxic units introduced with each intraspinal injection will depend on the antitoxic strength of the serum. It does not seem to be a common experience that the temperature rises after intraspinal injection.

5. It is not known just what happens with the antitoxin after it is injected into the spinal canal. Probably most of it is absorbed into the blood.

6 and 7. In treating tetanus, no time must be lost in excising or cleansing completely the infected area in order to remove as promptly and thoroughly as possible the source of the toxin. The treatment with antitoxic serum, which is not a general success seems to be based on the principle of introducing rapidly as much serum as can be done with safety by intraspinal as well as by intravenous or intramuscular injection. Details of serum may be found in the articles by F. W. Weed (The Medical Department of the United States Army in the World War 2 289, 1927) and by W. J. Stone (A Text-Book of Medicine by American Authors, edited by Russell L. Cecil, 1933, p. 123). Weed recommends that at least 5 000 units of tetanus antitoxin be given intrathecally as soon as possible. The injection should be repeated in twelve hours if the first injection does not contain 5 000 units. At the same time from 8,000 to 16,000 units is to be given intramuscularly. Both these injections

tions may be repeated daily for two or three days. Stone recommends the intravenous injection of 30,000 units thirty minutes after a desensitizing subcutaneous injection of 1 cc. If symptoms of uraphilaxis develop the intravenous injection should be suspended for three hours, after which the patient will probably be desensitized and can usually receive the full dose. Injection of 30,000 units intraspinally follows the intravenous injection. These injections are repeated on the second and third days and possibly also on the fourth. It is advised to inject 10,000 units intramuscularly on the eighth day to prevent a recurrence of symptoms from dormant bacilli or spores. For patients who react to a desensitizing dose of serum it has been recommended also that antitoxic serum be injected subcutaneously every half hour beginning with 0.03 cc and doubling with each injection until 25 cc has been injected, then in four hours 40 cc may be given and in six hours 100 cc (C W McClure in *Oxford Medicine* 5 202 1928). A report on the results of the treatment of tetanus by J K Calvin and A H Goldberg, appeared in *THE JOURNAL*, June 21 1930, page 1977.

PAIN REFERRED TO RENAL AREA

To the Editor—A woman aged 45 a widow had pyelocystitis in April of this year. Following the usual course of treatment the infection subsided, but there was recurrence. At this time a cystoscopic study was made which showed trigonitis normal kidney function pus and bacteria from both ureters (nongonorrheal) and normal pyelo-ureterograms. Following an irrigation of the renal pelvis and continuation of antiseptic treatment the infection completely disappeared. In the last three months the patient has been having severe colicky pain rotating between the bladder and the kidneys or involving them at the same time. There has never been any further pus in the urine in catheterized specimens nor have bacteria been present. Roentgenograms do not show stricture of the ureters. In spite of no strictures being demonstrable the ureters have been dilated three times and the renal pelvis lavaged. This has given no relief. A urologist in consultation called this condition a renal dyskinesia and since the patient is at the menopause suggested that ovarian extract be given hypodermically. This also failed to give relief. Atropine has been tried with negative results. Only morphine has relieved the pain. The attacks of pain in the last month have become more and more frequent and pain is now practically continuous. I am unable to find this complication mentioned in medical literature and would appreciate some references as to the nature of the complication and suggestions for treatment. M D Washington

ANSWER.—In reporting the clinical data the correspondent makes no mention of whether there is any evidence of renal stasis as shown by an estimation of residual urine in the renal pelvis or by means of urography. If there is no evidence of pyelectasis or ureterectasis, and judging from the description given there is none, it would be open to question whether the patient's pain is of renal origin. Pain of renal origin is rarely of a continuous nature, even though stasis may be present.

Although much has been written concerning pain of renal origin when evidence of pathologic change cannot be found there are comparatively few data to prove that such a condition exists. Relief of pain referred to the renal area has been reported following renal sympathectomy, but it has not been proved that the specific operation was the only factor in bringing about such relief. Among the articles that have been written on this subject may be mentioned 'Resection of the Nerves of the Kidney for Nephralgia and Small Hydronephroses' by E Papin and L Ambar (*J Urol* 11 337 [April] 1924) and 'Renal Sympathectomy,' by E Hess (*Pennsylvania M J* 33 741 [Aug] 1930).

One might well infer from the clinical description that the pain in this case is of extrarenal origin and if all other clinical lesions have been carefully excluded, one would be justified in assuming that it is of a functional nature. In the absence of pyelectasis, general treatment on a functional rather than an organic basis would seem advisable.

TUBERCULOUS PHLEBITIS

To the Editor—I have a case proved by biopsy to be tuberculosis of the anterior tibial vein. I can find no one to advise me as to how to handle it. If you have any literature on the subject or can direct me as to where to get advice I will be greatly appreciative of it.

R H COWLEY M D Berea Ky

ANSWER.—Tuberculous phlebitis has been repeatedly described by pathologists, chiefly since the classic description of Weigert on the venous tubercle in 1882. But not many clinical reports are known on the subject, most of them being in the European literature. Benda, one of the foremost students of vascular tuberculosis differentiates a periphlebitis, spreading in continuity from tuberculous foci in the neighborhood and invading the layers of the vein from the outside, from an endophlebitis or intimal tubercle, producing an endothelial erosion and secondary thrombosis. To these two avenues of infection Liebermeister

has added a possible invasion through the vasa vasorum, producing focal necrosis in the media and occurring near tuberculous foci, and a mode of infection through the lymphatics producing an exudative or caseous periphlebitis, occurring in the brain and retina, producing hemorrhages, infarcts and metastases to other veins.

In the given case, one would wish to know whether or not some other tuberculous infection of skin, tendon sheath or bone might not have invaded the vein secondarily. Assuming, however that the correspondent is dealing with a true vascular tuberculosis originating in the intima and producing a phlebitis obliterans, the management would depend mainly on the general status of the patient. Is there a massive pulmonary tuberculosis? Is there evidence of miliary tuberculosis? What is the patient's age? Generally speaking, if the patient is in good condition and the tuberculous phlebitis localized to one area, the most rational treatment would be a complete surgical excision. Should this be impossible because of the extent of the lesion or the existence of active tuberculous foci elsewhere in the body, roentgen irradiation of the tuberculous vein combined with a high saphenous ligation might be tried. The greatest danger in this type of lesion would be a sudden vascular dissemination of tuberculous bacilli leading to miliary tuberculosis. Finally if the patient is in a stage of disseminated tuberculosis in which the tuberculous phlebitis is just a partial picture any treatment outside of complete rest and general care would seem futile. The recent literature on the pathology of tuberculous phlebitis with references to older workers can be found in Löwenstein, E. *Tuberkel-bacillämie und Gefäßtuberkulose, Zentralbl f Bakt* 123 287 (April) 1933.

DIET IN ESOPHAGEAL STENOSIS

To the Editor—Kindly outline a diet for a boy aged 5 years suffering from complete stenosis of the esophagus who has to be fed through a gastrostomy opening. GEORGE A CAMPBELL M D Ottawa Ont

ANSWER.—A diet for a 5 year old boy with a complete stenosis of the esophagus, who must be fed through a gastrostomy opening into his stomach must be ample enough to provide for maintenance as well as for growth. The properly balanced amounts of carbohydrate, protein fat, minerals, vitamins and water should be contained in the diet of this child, in the same quantities and proportions as for the normal 5 year old.

The dietary may include milk eggs, vegetable soups, vegetables cereals, fruits, meats, fish, orange juice and cod liver oil. In these cases, however, even a well balanced, sufficient diet may fail to cause normal gain in weight and general nutrition may suffer. Chevalier Jackson (*Arch Pediat* 40 324 [May] 1923) has pointed out that if in these cases the child is allowed to masticate the food and spit the fluid food mixed with saliva into a funnel attached to the gastrostomy tube, an immediate improvement in nutrition and gain in weight follows. He concluded that under normal conditions a considerable amount of saliva is conveyed to the stomach between meals as well as that which is mixed and swallowed with the food and that the addition of the saliva to the food of those children was a desirable procedure.

FEEDING EXPERIMENTS WITH RATS

To the Editor—I am sponsoring a feeding experiment in the high school here with white rats. I should like to have general instructions for conducting such an experiment, the diets and so on. Can tooth defects be produced in rats as well as in puppies? If so how? Any information will be welcome and appreciated.

D W MATTHAEI M D Fessenden N D

ANSWER.—Rats should be selected of the same age, sex, and weight to be given the different types of diet. They should be about 28 days old and weigh about 40 Gm.

There should be a separate cage for each type of diet. The cages may be made by the students, wire screening being used for the sides of the cage a pie tin for the top, and a larger basin or pan for the bottom. Discarded cold cream jars or other small cups may be used for holding food and water. Clean newspapers may be used for covering the bottom. These papers should be changed daily, and the food and water cups kept filled.

The number and types of diets fed will depend on the age and interests of the students. In the first experiment it is best to compare but two or possibly three diets and to have these applicable to the group in question. The simplest and most effective one is to give one rat bread and water, the other bread and milk. The rats should be weighed at the beginning of the experiment and weekly thereafter, and their weight curves charted. When the difference between the two has become very marked (about two or three weeks) milk may

be added to the diet of the bread and water rat, and his progress followed. If it seems wise, milk may also be removed from the diet of the bread and milk rat.

Other types of diets typical in the community or luncheons chosen in the school lunchroom may also be used, as, for example, (1) bread, meat, potato, sugar, (2) whole wheat bread, vegetables, fruits, meat, (3) bread, butter, meat, vegetables, fruits, milk. These experiments will not show results as early or as spectacularly as the simple one described and will need to be carried out for a longer time. They are, however, well adapted to high school students. So far as possible the experiments should be planned and carried out by the students.

Tooth defects cannot be produced in rats and puppies, at least under conditions of experimentation possible in a schoolroom. The chief effects that can be observed are those of growth and general appearance, such as brightness of eyes, sleekness of fur and the like.

A complete set of directions for details of such experiments, including directions for making cages for the rats, has been prepared by Mrs. Ethel Martin of the National Dairy Council. Copies may be secured by writing the organization, 111 North Canal Street, Butler Brothers Building, Chicago.

CONSTITUENTS OF DENTAL PUS

To the Editor—A lay friend, an incorrigible microscopist, is asking embarrassing questions. Pointing to leukocytes in a fresh dark field of dental pus, he wants to know whether the sparkling particles with a brownish shimmie to be seen in the cytoplasm are phagocytized particles of extraneous material or what. Further, he asks whether the presence of these vibrant points is fraught with significance concerning the life, health or death of the containing cell, if not, how one can tell, distinguish and diagnose a live leukocyte from a dead pus cell by its appearance or behavior. He also asks what the swarms of highly motile spirilla are in the dental pus, the length about equal to the diameter of a leukocyte. They are occasionally seen in a dense huddle. Does this pertain to their reproductive activities? Is it likely that they are pathogenic?

DON HASTINGS DUFFIE, M.D. Central Lake Mich.

ANSWER—White blood cells known as granulocytes originate in the bone marrow and pass into the blood vessels by their own motility. They also pass through the vessel walls when attracted by infection or foreign bodies or certain chemical agents with a positive chemotaxis. They are living cells with lobed nuclei and hence are called polymorphonuclear cells. They possess amoeboid movement and can pass through the blood capillaries into the various tissues of the body. This is especially the case in so-called pyogenic infections.

The pyogenic bacteria attract the leukocytes in sufficient numbers to cause suppuration. The white cells are also phagocytic and can engulf bacteria and other foreign particles. The mobility, amoeboid movement and ingestion of bacteria and other particles are evidence of life in the leukocytes. These phenomena can be studied *in vitro*. The brownian movement displayed by the specific granules of the leukocytes is not characteristic of life. Many minute particles in suspension display a dancing or brownian movement. The granules stain with certain stains and are called neutrophilic, eosinophilic and basophilic. They are present in cells of bone marrow origin after they mature to the myelocyte stage or the adult granulocytes. These granules also take peroxidase stains which distinguish them from other blood cells. Phagocytized particles may be found in leukocytes, especially bacteria, red blood cells or foreign particles.

Many spirilla are found in dental pus, also various cocci, as streptococci, staphylococci and pneumococci. The most common spirilla are *Vibrio sputigenus*, *Spirochaeta microdentium* and *macrodentium*, *Treponema mucosum*, and the spirochetes of Vincent's infection known as *Spirochaeta vincenti*. In syphilitic primary or secondary mouth lesions, *Spirochaeta pallida* can be demonstrated with the dark field.

MALDEVELOPMENT OF EAR

To the Editor—I delivered a primipara of a living female child in breech presentation. The child, weighing $7\frac{1}{2}$ pounds (3400 Gm.) was apparently normal. This morning the woman taking care of the case called to my attention the right ear, the outer auricle of which is not as fully developed as the left. On closer examination there is no development as regards the canal or a tumor that can be determined externally, and the auricle is slightly underdeveloped. The left ear is normal in all respects. Is there anything to be done now or later or is this primarily maldevelopment?

WILLIAM KLANN, M.D. Wellington, Ohio

ANSWER—The deformity is due to a lack of development of the auricle and the external auditory canal. However, this does not give any information regarding the actual hearing ability of the child so far as the inner ear is concerned. In some of these cases there is also lack of development of the middle or possibly the inner ear, in which case the hearing would be either very defective or wholly absent. In so young a child it is impos-

sible to test the hearing properly, but when it can be done in later years it will be time enough then to decide whether a plastic operation should be done. The latter is usually performed for esthetic purposes, not as an aid to hearing. Even if there is an absence of the external auditory canal, the hearing is usually quite good if the middle and inner ear are well developed. At the present time no operative work is indicated.

COCCIDIOIDAL GRANULOMA

To the Editor—Information is desired regarding possibilities and probabilities of industrial origin of two cases of coccidioidal granuloma that recently occurred in this vicinity. Two men employed on a construction job digging a pipe line died from a disease diagnosed as coccidioidal granuloma. Question has come up whether or not the industrial hazard, as from the inhalation of dust or the spread of the disease from one man to another, is a factor. If published please omit my name and city.

M. D., California.

ANSWER—Coccidioidal granuloma is an acute infectious disease due to *Coccidioides immitis*. Some doubt still exists as to this organism being a protozoan or a mold. It is stated widely to be closely related to *Oidia* and *Hyphomycetes*. The greater number of cases have appeared in California and particularly in the San Joaquin Valley. Frequently it is termed 'California disease'. Infection takes place with fair frequency among raw fruit handlers. This at once suggests the possibility of an occupational origin when present in this class of workers. The organism or at least its spores has been detected in the soil by Stewart and Meyers. This in turn makes possible the association of the disease among ditch diggers with an occupational origin, particularly in the state of California. Inhalation of the spores possibly constitutes the commonest mode of entry into the body. Pulmonary lesions are the commonest encountered. Transmission from animal to animal is well known and from man to man is uncertain but is regarded as within reason, as the organisms are readily found in the discharge from lesions and, in the case of skin lesions, probably are easily transferred from person to person. The two deaths mentioned among pipe line trench diggers may practically be associated with work as the source if the organism or its spores may be detected along the ditch area. If not found the situation becomes one of speculation and conjecture. General information may be found in the following publications:

- Dickson E. C. *Oidiomycosis in California with Especial Reference to Coccidioidal Granuloma*. *Arch. Int. Med.* 16: 1028 (Dec.) 1915.

INFECTION OF BOWEL WITH CHEESE MITES

To the Editor—A woman aged 24 has been having diarrhea with from five to eight stools a day for the past three months. The stools are watery, not offensive and show no trace of blood. Microscopic examination of the stool shows the presence in great numbers of *Tyroglyphus siro* (cheese mites) both in the adult and in the encysted form. Could this be causing the excessive diarrhea and if so what is the treatment for it? I can find only the slightest reference to it in the books I have. I would appreciate anything you might suggest in the line of treatment. I would appreciate a reply as soon as possible since the patient is becoming quite anemic.

H. B. SPAULDING, M.D. Ralston, Okla.

ANSWER—Mite infestation in the human intestine, genital tract and skin has been reported widely but not frequently, especially among the handlers of dried fruits, copra and cereals in whom the mites produce a dermatitis. Intestinal infestations have recently been reviewed by Hinman and Kampmeier. The cheese mite *Tyroglyphus siro* Linn., notorious for its abundance in the 'Altenburg mite cheese,' has been charged with producing intestinal disorders in those who have eaten too much of this delicacy. Banks has named a mite found in cheese in the United States *Tyroglyphus americanus*. The two authors referred to report two cases of diarrhea associated with an abundance of mites (*Tyroglyphus longior* Gervais) in the stools. In one of these cases the diarrhea was accompanied by scattered rectal ulcers negative for amebae. The mites disappeared from the feces and formed stools were reported after six days of controlled diet in the hospital. Continuous reinfestation from eating mite-contaminated food has been suggested as the cause of the continuation of the symptoms. The articles mentioned are as follows:

- Hinman E. H. and Kampmeier R. H. *Intestinal Acariasis Due to Tyroglyphus longior Gervais*. *Am. J. Trop. Med.* 14: 355 (July) 1934.
Kampmeier R. H. and Hinman E. H. *Mite Infestation in the Human Intestine*. *South M. J.* 27: 273 (March) 1934.

POLLEN IN MICHIGAN

To the Editor—Can you offer any private information as to climatic and local atmospheric conditions of Alpena Mich. as it would influence a person afflicted with hay fever and asthma? A relative of mine a professional man is now living in Chicago where he suffers greatly from his thorn in the flesh. He has been told that Alpena Mich. is free from hay fever and that a change to that locality will probably prove very beneficial to him. In hopes that his condition may be improved by taking up his residence in Alpena he is considering moving there. I shall greatly appreciate your opinion regarding the local conditions prevailing in Alpena as they may be likely to influence a hay fever and asthmatic patient.

F O GIERE MD Minneapolis

ANSWER—In offering an opinion on the climatic and local atmospheric conditions of Alpena Mich. we are limiting this answer to a consideration of the probable incidence of ragweed pollen and are disregarding such factors as temperature and humidity which in hay fever at least are not regarded as of prime importance.

A report that any locality in northern Michigan is free from hay fever is a rather broad statement but the suggestion that the change would prove beneficial is probably true. No statistics on the pollen content of the air for the immediate vicinity of Alpena during the fall season are available, but it is known that ragweed pollen is almost as prevalent at Bay City (100 miles south of Alpena) as in Chicago. More than likely, however, conditions at Alpena are more like those found at Petoskey and St Ignace, where the concentration of pollen during the fall season is only about one seventh as much as in Chicago. It is possible that prevailing southwest winds coming from the land would bring more ragweed pollen to Alpena than to Petoskey. At the latter place, most of the pollen encountered is not produced locally but is blown to the vicinity when the wind happens to be from the southwest south or southeast. One could expect at least eight or ten days of hay fever symptoms each season at Alpena. Localities that are entirely free from ragweed pollen should be considered before deciding on a change of residence.

MAYONNAISE RECIPE WITH LIQUID PETROLATUM—
DEXTROSE IN SCLEROSING SOLUTIONS

To the Editor—Please give a recipe for making mayonnaise with petrolatum (or other dressing) as used in some reduction diets. Dextrose in 5 per cent solution is used as a sclerosing agent in the treatment of varicose veins. When the same solution and strength are used intra-venously in the arm to combat shock or prior to operation why does it not subsequently sclerose and close this vein? Please omit name.

MD Washington

ANSWER—Mayonnaise suitable for a reduction diet may be made after this formula:

- 1 egg
- 2 cupfuls of liquid petrolatum
- 1 teaspoonful of salt
- 1 teaspoonful of mustard
- Paprika to taste
- Blade into an emulsion

It is 50 per cent rather than 5 per cent of dextrose solution that is employed for producing sclerosis of varicose veins. Even 50 per cent solution may be injected intravenously without producing sclerosis, by delivering it drop by drop (which minimizes the effect on the intima) and by introducing it into a vein the circulation of which is active so that the blood current dilutes it at once. There is little current in a varicose vein and the sclerosing injection is given in such a way as to secure maximum local action on the intima.

HEAD INJURIES WITH SLOUGH OF BRAIN TISSUE

To the Editor—Mrs W. aged 45 was brought into the hospital after being struck by an automobile. She was unconscious and there was bleeding from the right ear and right side of the nose associated with spinal fluid. Also she passed a large piece of brain tissue with other small particles of tissue from the right ear. She was unconscious for ten days and since then has gradually improved each day, both physically and mentally. Roentgen examination reveals a linear fracture about 4 inches in length involving the posterior portion of the right parietal bone extending into the region of the middle fossa of the skull and the base of the skull. Please advise me as to the prognosis of the future and whether or not there are many cases on record in which patients have lived after a fractured skull with the passage of brain tissue.

WILLIAM S WEISMAN MD Forest Hills Mass

ANSWER—It is not rare for patients who have sustained a severe skull fracture to slough out small pieces of contused brain, although this is of course by no means common. It is difficult to answer the question as to prognosis without knowing more as to the patient's exact condition at present and as to the length of time that has elapsed since the injury. One

sees comparatively minor head injuries that produce rather major mental and neurotic changes and one also sees cases in which extensive mechanical damage has failed to produce any permanent mental disability worthy of note.

POSSIBILITY OF NEGRO CHILD FROM WHITE PARENTS

To the Editor—Several of my acquaintances know of many supposedly authentic instances in which two white parents have begotten Negro children and have discovered later that there was some small percentage of Negro blood in one of the parents. It is my contention that such occurrences are very improbable or impossible as the inheritance of human skin pigmentation does not follow Mendel's law so simply as is the case with the hair pigmentation of rabbits and other animals but that human skin pigmentation is always very nearly a blend of that of the parents. I would appreciate an expression of your opinion regarding this matter. Please omit name.

MD Minnesota

ANSWER—Studies by the Davenports on the genetics of skin color in Negro-white crosses indicate that two nearly white hybrid parents can have offspring somewhat darker than themselves, but it is not genetically possible for nonhybrid white parents to have 'Negro children' unless a melanic mutation should occur. Such mutations are extremely rare, if they occur at all. The appearance of a Negro child from white 'parents' has a simpler explanation, which will occur to any one.

OLIVE OIL AND ELIMINATION

To the Editor—I understand that some able physicians recommend a teaspoonful of olive oil before meals four times daily for successful correction of faulty elimination with a trace of salt to render it more palatable if preferred. It is said that if the patient is underweight he is restored to normal and if overweight is reduced to normal height and age considered. There appears a widespread prejudice against olive oil under the impression that it invariably increases weight. Your opinion or that of others would be much appreciated.

J W RIECKE MD St Louis

ANSWER—A teaspoonful of olive oil four times daily before meals would hardly serve as a cure for constipation because, according to most authorities, about 97 per cent would be digested and used in the upper part of the bowel. Accordingly, but little would be left either to increase the volume of the feces or to lubricate the colon. Four teaspoonfuls of olive oil could hardly affect a person's weight much because if all of the fat was digested it would give the body about 200 calories. The addition of 200 calories to the diet could hardly put much weight on a thin person.

PUERPERAL SEPSIS AND APPENDICITIS

To the Editor—In your treatment of puerperal sepsis and appendicitis with abscess formation (THE JOURNAL January 12 p. 136) you state three methods of drainage: posterior vaginal section, extraperitoneal with incision just above Poupart's ligament, and if either of these are impossible you advise laparotomy. All would agree with this treatment especially in appendicitis but in puerperal sepsis I think it would be wise to advise to wait for the abscess to point to the cul-de-sac or broad ligament. Also should you not have added to your treatment the use of the Elliott machine to aid in the localization of the abscess? Would there be any effect from large amounts of alcohol other than its food value and its use as an appetizer? Quinine may merit some of its past reputation. Its action is probably the same as that of ergot and of solution of pituitary which you recommend.

A MORGAN DEARMAN MD Parkersburg W Va

RIDING HEAD FORWARD ON TRAINS

To the Editor—In regard to the query of D A Laird PhD (THE JOURNAL March 9) as to the reason for the head forward position in train berths one reason not mentioned in your reply has seemed to me to be that with the usual ventilation, smoke, cinders, dust and drafts are more of an annoyance with the head to the rear of the berth of a moving train. However it has always seemed to me that the probability of skull and neck injuries from sudden impact in head on collisions must constitute a real danger with the head forward position as now used. It would be really interesting to know to what extent head and neck injuries do occur under such conditions with the head forward. Please omit name.

MD California

HISTAMINE IN URTICARIA

To the Editor—In Queries and Minor Notes in THE JOURNAL January 26 page 340 C G Gray asks about the use of histamine in the treatment of urticaria. Your reply states that search of the literature fails to reveal any article dealing with the use of histamine injection in the treatment of seasonal urticaria or any other form of urticaria. Permit me to call your attention to the Use of Histamine in the Treatment of Pruritus by Ernstene and Banks THE JOURNAL Feb. 4 1933 page 328.

Book Notices

Physiology in Modern Medicine By J. J. H. Macleod M.D. D.Sc. Regius Professor of Physiology in the University of Aberdeen Scotland. Assisted in the present edition by Philip Hard Professor of Physiology Johns Hopkins University School of Medicine Edward I. Carter Adjunct Professor of Medicine Johns Hopkins University J. M. D. Olmsted Professor of Physiology University of California J. M. Peterson Lecturer in Experimental Physiology University of Aberdeen and A. R. Taylor Professor of Physiology, University of Toronto. Seventh edition Cloth Price \$6.00 Pp 1154, with 297 illustrations St. Louis C. V. Mosby Company 1935

In the preface to the latest edition of this standard work it was pointed out by Professor Macleod that the word "biochemistry" was removed from the title because the subject to which it applies has expanded greatly and has now become a science associated with physiology rather than a part of physiology. Also in the new edition the bibliography has been placed at the end of the volume instead of at the end of each section. The bibliography has also been brought down to the present and made more complete. In the new revision the section on the neuromuscular and central nervous systems has been completely rewritten by a new author, as has also the section on circulation. This book has made itself an excellent place in the literature of medicine. If there are any specific criticisms to be made they concern the inadequacy of the index, which is far too limited for a work of this scope and also the fact that repeated printings have resulted in enough wear and tear to the type to demand a complete resetting before another edition is undertaken. The alternate light and dark lines resulting from the insertion of the new material give the book an exceedingly spotty appearance.

Biologische Untersuchungen über Farbstoffe. Band I. Von Dr. Iwano Matsuo Professor der Medizin in Kyoto. Cloth Pp 404 with illustrations Kyoto 1934

This is a collection of papers by Dr. Matsuo and his students. It is to be completed by the publication of a second volume, the table of contents of which is given. The series will make much of this valuable material available to the accidental reader for the first time, as many of the articles were originally published in Japanese. After a section of summarization, detailed studies are included on the physical chemistry, pharmacology and excretion of dyes. Under physical chemistry are included studies by electrophoresis of 113 acid and eighty-one basic dyes. There are also studies of the diffusibility and lipid solubility of dyes and of their behavior in the presence of different serums, of erythrocytes and in organ extracts, with interesting but restrained conclusions about the influence of these factors. By far the largest part of the volume is devoted to dye excretion by the liver and kidneys. This is studied experimentally with a number of dyes under normal conditions and with many modifications, including India ink injections, bile duct ligation, splenectomy, liver damage with drugs, parasites, bacterial toxins or poison gases, or renal damage with poisons or after the extirpation of one or both kidneys. The use of azorubin S is recommended for liver function tests, but no mention is made of bromsulphalein. One of the most interesting papers is Takahashi's experimental study of a long series of drugs in biliary infections. In general he found that the basic dyes exerted more bactericidal action than the acid dyes with the exception of mercurochrome, which showed striking bactericidal action, which was reduced by long contact with bile. Of the large number of dyes so studied which did not include flumerin only nine remained bactericidal after excretion through the liver. Studies in patients demonstrated the bactericidal action of acriflavine hydrochloride and of mercurochrome on typhoid bacilli, which was confirmed for mercurochrome in three of the experiments with rabbits given cholecystitis with typhoid bacilli. Flavocid exerted the strongest bactericidal action against *B. coli* and staphylococci as compared with acriflavine hydrochloride and mercurochrome. One is impressed by the enormous amount of carefully organized work represented by these papers, which should be available for reference for all workers in this field. It should be noted that the experiments seem to have been done with commercial dyes, impurities in which might be sources of error. Nevertheless, the book presents a mass

of material that should be of value for future work. It is in no sense a general review and therefore lacks certain comprehensive discussions that might be of value, and it is bibliographically incomplete. It is to be hoped that a good index will be included in the second volume, as this is indispensable for complete usefulness.

The Struggle for Existence By G. F. Gause Zoological Institute of the University of Moscow. Cloth Price \$3 Pp 163 with 41 illustrations Baltimore Williams & Wilkins Company 1934

This attempt at a mathematical analysis of the processes of natural selection comes from the Laboratory of Ecology of the University of Moscow, but its genesis is traceable to the teachings and investigations of Dr. Raymond Pearl on the laws of population. In his foreword Dr. Pearl deplores the pitiful meagerness of all the attempts to portray the mechanics of natural selection by experimental and statistical methods since Darwin published his *Origin of Species* in 1859.

Population problems are basically biologic. They deal with the struggle for existence and natural selection, which are aspects of the dynamics of population dealing with birth rates, death rates, and interrelations of organisms in mixed populations. Since they are dynamic, they lend themselves to measurement and thus to mathematical analysis.

The author recognizes the difficulties in his path, the complexity of biologic problems, the determination of the types of mathematical procedures to fit the problems in hand, and the interpretation of the significance of the results. Nevertheless, he makes a beginning with a homogeneous population of the simplest types of organisms in an isolated and controlled environment. His results lead to the conclusion that the Verhulst-Pearl logistic curve expresses quantitatively the struggle for existence that takes place between individuals within a homogeneous group.

From this simplified basis he next proceeds to analyze the competition between two different kinds of yeast cells mingled in one culture medium and finds that his results coincide with Volterra's equation and express competition between species in terms of the growing population themselves. He interjects the caution that "Only in those cases, where the results deduced from equations are confirmed by the data obtained through entirely different methods, by a direct study of the factors limiting growth, can we be sure of the correctness of the quantitative theories." If the properties of two species growing separately, i.e., their coefficients of geometric increase, their maximal volumes, and alcohol production per unit of volume when alcohol limits the growth, are determined and these values are connected into a theoretical equation of the struggle for existence, one can calculate in what proportion a certain limited amount of energy will be distributed between the populations of two competing species. This means that one can calculate theoretically the growth of species and their maximal volumes in a mixed population. The equation of the struggle for existence expresses the idea that a potential geometric increase of each species in every infinitesimal interval of time is realized only up to a certain degree depending on the unutilized opportunity for growth at that moment, and that the species possesses certain coefficients of seizing this unutilized opportunity. These results hold only under aerobic conditions, owing to the fact that under anaerobic conditions waste products complicate the situation.

The competition between two species of ciliate Protozoa for a common food supply lends itself to mathematical analysis. In the first period the two species compete for the still unutilized sources of energy. The proportion in which this energy is distributed between the two species is determined by the system of Volterra's differential equations of competition, but the coefficients of the struggle for existence in these equations change during the growth of the population and become more complicated. In the second period there is a redistribution of the completely seized energy between the two species, which is again controlled by the differential equations of competition. The species with the greater value of the coefficient of multiplication eventually drives out the one with a lesser value.

A study of a protozoan population consisting of a predator and its prey did not exhibit the classic oscillations in numbers assumed by Lotka and Volterra but was to be explained by

special biologic adaptations. In another combination lacking such adaptation, the expected oscillations occurred.

It is to be noted that in all these elementary studies of population the organisms are isolated under control and are presumably exempt from disease (except such as may possibly be due to genetic defects). In nature one of the great factors in the destruction of the individual is disease. This too has a selective action and resistance to it a survival value. How far the higher mathematics of the study of populations will aid in the analysis of these still greater complications resulting from the introduction of the pathogenic into the struggle for existence, only the future can reveal.

Langographie cérébrale. Ses applications et résultats en anatomie physiologie et clinique. Par F. MAS MONIZ, professeur de neurologie à la Faculté de médecine de Lisbonne. Paper. Price 90 francs. Pp. 327 with 192 illustrations. Paris: Masson & Co. 1931.

This work on cerebral angiography represents the author's experience with the method over a period of three years. The present volume is the result of the author's attempt to visualize the cerebral arteries radiographically but the perfection of his technic and his many unique applications of the method have enabled him to produce a beautiful series of roentgenograms illustrating the localization and diagnosis of brain tumors, cerebral varices, aneurysms of the cerebral arteries and angiomas. He has also been able to demonstrate many interesting anatomic features of the cerebral circulation such as the passage of the opaque solution through the arterial circulation, the capillaries and the veins. He further demonstrates the meningeal circulation. By a series of films made at short intervals after the injection of the opaque solution many unusual roentgenograms are produced to illustrate the cerebral circulation. Formerly the author used a 25 per cent solution of sodium iodide for the injection preceded by the administration of phenobarbital and morphine. With this technic untoward results were encountered in cases of arteriosclerosis, toxemias and uremias. With the introduction of thorium dioxide sol as an opaque medium the author carried out a series of experiments to determine the effect of this solution when injected into the skin under the skin and intramuscularly. No undesirable reactions were encountered. Since limiting himself to the use of this medium for angiography, the author has found no undesirable reactions even in the types of cases in which the sodium iodide produced undesirable reactions. The technic consists essentially in cutting down on the common carotid artery and with a small caliber needle injecting from 0.5 to 1 cc. of solution. If there is no reaction he completes the injection of from 8 to 13 cc. of the thorium dioxide sol. Films are made at intervals of one second during the injection, a rapid exposure of about one-tenth second being used. The illustrations are unusually clear and interesting and they definitely demonstrate such unusual entities as cerebral varices, angiomas, vascular and avascular tumors and hydrocephalus. This volume represents an excellent atlas on the subject. While of special interest to the neurologist, neurosurgeon and radiologist, the book will be of unusual interest to any one interested in a really epochal advance in the diagnosis of intracranial lesions.

Modern Operative Surgery. Edited by G. Grey Turner, M.S., F.R.C.S., F.A.C.S., Senior Hon. Surgeon, Royal Infirmary, Newcastle upon Tyne. In two volumes. Second edition. Paperbound. Price \$16 per set. Pp. 868 with 871 illustrations. Baltimore: William Wood & Company, 1934.

This is a symposium by twenty-seven British surgeons. The first edition was issued in 1925 by H. W. Carson and is now revised by G. G. Turner. It is the result of an attempt to present to the profession an authoritative survey of the whole range of modern surgical operations, including those on the eye, ear, nose, throat and nervous system. The closely written text furnishes details of preoperative preparations and points out difficulties and dangers arising during or after surgical procedures. Overlapping, nearly unavoidable in a cooperative work, has been reduced to a minimum but one is surprised to note an unevenness and lack of balance in the consideration allotted to various subjects. The surgery of the spinal cord and the sympathetic system, for example, is described in great detail. On the other hand such an important subject as thyroidectomy has been treated in a stepmotherly fashion, the discussion of indications for blood transfusions is meager and new apparatus

is not described. Of the many solutions used for injection of varicose veins only sodium salicylate and quinine and urea are cited. In the chapter on intestinal obstruction the diagnostic value of roentgenograms and the therapeutic value of transduodenal decompression with the nasal catheter have not been pointed out. The subject of hernias is inadequately covered, one looks in vain for a description of Ferguson's or Girard's operation. The value of the resectoscope in prostatic surgery is not discussed. Placing of bibliographic references in the text and not at the foot of the page is disturbing. Furthermore references are made almost exclusively to publications twenty or more years old. The quality of illustrations is mediocre and their style old-fashioned. Several chapters, particularly those written or revised by Turner, are excellent, sections on abdominal surgery and neurosurgery are well presented. The aim and scope of this work are so large that space probably did not allow a more detailed description of the technic; therefore the book will have its greatest appeal to a young surgeon for whom in spite of its minor flaws it will furnish an immense wealth of information in lucid sequence.

L'année électro radiologique. Par MOREL KAHN avec la collaboration de MM. C. Bonte, A. Devols, C. Duclaux, T. Fainsliber, H. Fleischgold, J. Guilhem, R. Humbert, I. Marques, W. Strouzer et L. Stuhl. Première année. Paper. Price 40 francs. Pp. 232 with 23 illustrations. Paris: Masson & Co. 1934.

This is the first of a series of year books on electroradiology written by the author and a number of collaborators. The more recent contributions to the field of diagnostic roentgenology are discussed in the first chapter. Of special interest are the recent advances in soft tissue radiography, intravenous urography, the Proetz displacement method for the visualization of the nasal sinuses and mucosal relief examination of the gastro-intestinal tract. The section on radiotherapy presents some interesting contributions on the use of roentgenotherapy in acute inflammatory processes. The Coutard method for the radiologic management of cancer is discussed. A chapter dealing with the complications arising from the use of radium in the management of carcinoma of the uterus is interesting and important. Finally there is a summary of the question of 500,000 volt therapy. The third section of the book deals with the more recent contributions in the field of physical therapy and the final chapter presents a rather novel idea in giving an outline of the more important international radiologic meetings of the year. The book will be of interest especially to the radiologist.

The Treatment of Common Female Ailments. By Frederick John McCann, M.D., F.R.C.S., F.C.O.G., Consulting Surgeon, Samaritan Free Hospital for Women, London. Third edition. Cloth. Price \$4.75. Pp. 379. Baltimore: William Wood & Company, 1934.

The demand for this work by the general practitioner provided the opportunity for complete revision and additional new material. This edition contains a great deal of useful information ably presented augmented by illustrative case reports from the author's personal experience. The subject of medical gynecology is fairly well covered and each subject is treated from the standpoint of practical management.

The book is well organized, is printed on good paper with readable type, and is fairly free from errors. The statement "the clotting of menstrual blood is said to be due to a tryptic ferment contained in the premenstrual secretion of the uterine glands" (p. 72) is one exception. The author probably means that the nonclotting is due to the action of a tryptic ferment, in accordance with the view of Oskar Frankl. Another error is found on page 115 in the discussion of vaginitis, *Trichomonas vaginalis* being mentioned in place of *Trichomonas vaginalis*. It is regrettable that he did not dwell at greater length on this form of vaginitis, which is encountered so commonly and which has proved so refractory to treatment.

His advice in the use of the operation of curettage in menorrhagia is sound, but his opinion regarding the role of alcohol and the use of contraceptives in the causation of menorrhagia may be challenged.

Wholesome advice is given to the physician concerning the upbringing and education of girls in the chapter on the prevention of female ailments.

The book will be found useful to physicians in general practice. It is not illustrated.

Physiologie et pathologie du système réticulo endothélial Par Albert H. Du Bois, chef de clinique à la clinique médicale universitaire de Gendres. Préface du Professeur M. Roch. Papier. Price 36 francs. Pp 204. Paris: Masson & Cie 1934

In this monograph the author reviews many of the contributions to the subject of the reticulo endothelial system particularly those made between the years 1925 and 1930. The bibliography of 588 papers will be of value to all workers in the field. The book consists of eighteen chapters in which such phases as the morphology of the mesenchymal tissues, achievements of vital staining, and the physiologic and pathologic activities of reticulo-endothelial tissues are considered. The presentation is more descriptive than analytic but represents an enormous amount of labor in assembling the more recent evidence concerning the important functions of the active mesenchyme. Particular emphasis is placed on the relationship to immunity, allergy, abnormalities of lipid metabolism and chemotherapy. The style is simple and direct and the index has been carefully compiled. The monograph is an excellent summary of progress during a five year period of significant activity in the development of the reticulo endothelial concept.

The Clinical Aspects of Visceral Neurology with Special Reference to the Surgery of the Sympathetic Nervous System By W. K. Livingston M.D. Clinical Associate in Surgery University of Oregon Medical School. Cloth. Price \$7. Pp 214 with 46 illustrations. Springfield Ill. & Baltimore Charles C. Thomas 1934

This monograph is based on the author's personal observation of 300 cases requiring visceral nerve surgery studied closely before and after operation. Livingston divides his subject matter into three parts: the structure and functions of the visceral nervous system, clinical conditions treated by visceral nerve surgery and surgical procedures. The first part contains the structure and functions of the visceral nervous system which is further divided into four chapters in which the anatomy of the visceral nervous system, physiology and pharmacology, visceral pain and the normal regulation of blood vessel function are discussed in simple and easily understandable language. The second part is divided into five chapters in which the clinical conditions treated by visceral nerve surgery are discussed. The author describes cases of Raynaud's disease, erythromelalgia, scleroderma, hypertension and occlusive diseases of the blood vessels in which operation was performed and gives the results obtained. The postoperative results of cases of chronic arthritis, angina pectoris and pelvic disorders are also given. The last part consists of a discussion of the prognostic methods used in determining the status of the involved areas and the mechanism and technique of the various surgical procedures used on the sympathetic and the somatic nervous system. There is an excellent bibliography for the student interested in visceral neurology and the surgery of the sympathetic nervous system. Many of the author's views on the physiology of the visceral nervous system are controversial but he pleads for more work in this regard in the hope that these controversial points may be settled accurately.

A Manual of Biochemistry By J. F. McClendon, Professor of Physiological Chemistry University of Minnesota Medical School. Cloth. Price \$5. Pp 381 with 56 illustrations. New York: John Wiley & Sons Inc. London: Chapman & Hall Ltd. 1934

The title and size of this book would lead one to expect an elementary, brief and practical textbook of biochemistry. The work is exceedingly elementary and brief in some respects but it becomes rather involved and specialized in others. The book is unique in many respects. This uniqueness resides in the authors curious style in the lack of orderly presentation in many exceedingly misleading statements in the peculiar order of presentation, in the questionable choice of material and in the addition of rather inappropriate and often poorly reproduced illustrations. The text is divided into six parts. Part I is a disconnected introduction covering a great variety of factors. Part II, entitled 'Inorganic' includes most of the inorganic elements, radiation in therapeutics and permitt in water softening. Part III, entitled 'Organic' develops too briefly the chemistry of carbohydrates, lipins and proteins. One wonders why benzoic acid is included under proteins and why citrullin is never referred to even in discussing urea formation in a later chapter. Part IV, entitled "Nitrogenous Bases, curiously

includes hematin, bilirubin and chlorophyll. The composition of foods, digestion, metabolism and excretion are treated with entirely too much brevity, only two and one half pages on metabolism. One wonders again why one paragraph is devoted to the entire endocrine system in the section on excretion. Part V is devoted to an unorganized collection of laboratory experiments often again of peculiar choice for a textbook of this scope and grade. Part VI is an alphabetically arranged list of some thousand substances from sodium to water with their more common physical and physiologic properties. Such important substances as glycuronic acid, theelin, thecolol, citrullin, saccharase and emulsin are omitted, while such an odd substance as cimicic acid, which "occurs in bedbugs," is listed.

Donnoch Landarzt! Erfahrungen und Betrachtungen aus der Praxis Von Dr. August Heider. Second edition. Paper. Price 4.80 marks. Pp 229. Munich: Verlag der aerztlichen Rundschau Otto Gmelin 1933

This book is written by a country doctor in the Black Forest of Baden. Living in Koenigsfeld he practices throughout a large highland district embracing ten hamlets and a considerable peasant population. He is also chief of a sanatorium and a children's home and physician in charge of a large private school. Well trained by six years of assistantship in the universities and clinics of Freiburg, Munich, Bonn, Marburg and Heidelberg he has also profited by a large professional experience and a talent for observation to form independent judgments of a great number of medical problems of all kinds that present themselves to general practitioners. He discusses with many interesting illustrations psychotherapy, the sex problems, homopathy toward which he is quite sympathetic, and the relation of country doctors to medical schools and clinics. He then gives his experiences and methods of treatment in obstetrics, dietary problems, allergic disorders, blood transfusion, hypertension, infectious diseases, tuberculosis and the psychoses. Although a few of the author's theories and therapeutic recommendations may not be in accordance with the general opinions of the majority of physicians the book will interest both rural and city practitioners who will equally admire the author's striking verbal pictures and his shrewd observations on modes of medical practice.

Voluntary Sterilization By C. P. Blacker M.C. M.A. M.D. General Secretary of the Eugenic Society. Cloth. Price \$1.75. Pp 145. New York & London: Oxford University Press 1934

This volume begins with a history of sterilization in England, leading up to the sterilization bill, which has resulted from the so called Brock report. There is a brief statement as to the nature of sterilization operations and then a general discussion of laws relating to sterilization. This concludes with the statement that 'the social injustice which arises from the present uncertain state of the law about sterilization is one of the strongest arguments in favor of the whole subject being cleared up by the passing of a carefully drafted sterilization law'. There follows a chapter on hereditary defects and diseases and then a discussion of the fertility of the defective producing classes.

In his discussion of sterilization in other countries, Dr. Blacker indicates the highly confused situation that exists in the United States. The explanation of the situation seems to be that the enthusiasm of small groups secured the passage of legislation for which there was no general demand and no sufficient backing of public opinion. Sterilization laws will succeed only when public opinion is enlisted to support them. The objections to sterilization are marshaled in a chapter with this title, the volume concluding with an analysis of the available literature on the inheritance of mental deficiency.

Old Age—Medically Considered. A Series of Papers by Medical Authorities on the Physical and Dietetic Treatment of Diseases and Disabilities of Old Age By Medical Authorities. With a foreword by R. King Brown B.A. M.D. D.P.H. Reprinted from the British Journal of Physical Medicine. Paper. Price 3/- Pp 96 with illustrations. London: Actinic Press Ltd. 1934

This volume is a collection of articles previously published in the *British Journal of Physical Medicine*. It is full of practical advice relative to the care of the aged, written by a number of competent British authorities. The essays are quite short but sufficiently long to provide innumerable excellent suggestions.

Medicolegal

Workmen's Compensation Acts Pulmonary Asbestosis an "Injury by Accident," Not an Occupational Disease—McNeely brought a common law action for damages against his employer, the Carolina Asbestos Company. He alleged that the atmosphere in the room in which he worked for some fifteen months was heavily impregnated with asbestos dust, that his employer negligently failed to provide a dust or suction system or any proper ventilating system, and that because of the employer's negligence he inhaled such quantities of asbestos dust during his employment that he became afflicted with pulmonary asbestosis. The trial court holding that the workman's disability was compensable under the workmen's compensation act of North Carolina and that he should have proceeded thereunder rather than at common law, rendered judgment for the employer. McNeely then appealed to the Supreme Court of North Carolina.

The workman contended that the workmen's compensation act applies only to an 'injury by accident' arising out of an employment. Since pulmonary asbestosis, he argued, develops slowly and progressively, it is an occupational disease and not an 'injury by accident' and is not, therefore, covered by the compensation act. The term 'occupational disease,' said the Supreme Court, has been variously defined and interpreted in judicial decisions and textbooks. Schneider in his 'Workmen's Compensation Law,' vol 1 (ed 2), p 644, states that

A disease contracted in the usual and ordinary course of events which from the common experience of humanity is known to be incidental to a particular employment is an occupational disease and not within the contemplation of the Workmen's Compensation Law.

And the Supreme Court of Iowa, in *Gay v. Hocking Coal Co.*, 184 Iowa 949, 169 N. W. 360, said that

An 'occupational disease' suffered by a servant or employee if it means anything as distinguished from a disease caused or superinduced by an actionable wrong or injury, is neither more nor less than a disease which is the usual incident or result of the particular employment in which the workman is engaged as distinguished from one which is caused or brought about by the employer's failure in his duty to furnish him a safe place to work. If the employer fails to provide a reasonably safe place to work or fails to observe the specific requirements of the statute with respect thereto and as a result of such neglect the employee is injured the liability of such employer cannot be avoided by calling such injury an occupational disease or by showing that disease of that nature is often the accompaniment or result of such employment, even when all due care has been exercised by the employer.

Assuming the correctness of these definitions, continued the Supreme Court, and considering the facts of this case, it is obvious that McNeely's ailment was not an occupational disease. He testified that he had worked in a similar capacity in another asbestos plant for about eleven years prior to his employment with the defendant without suffering any ill effects from the work. His injury, then, was not produced by the inherent nature of his work itself, and classifiable as an occupational disease, but was produced rather by the active negligence of the employer in failing to maintain a dust or suction system such as is in general use in other asbestos plants.

The Supreme Court moreover concluded that McNeely's ailment or injury was accidental within the meaning of the compensation act. In *Conrod v. Cook-Lewis Foundry Co.*, 198 N. C. 723, 153 S. E. 266 said the court, this court, in construing the term "injury by accident, as used in the workmen's compensation act, said

The word accident as used here has been defined as an unlooked for and untoward event which is not expected or designed by the person who suffers the injury.

It seems to be generally conceded that if a workman should suddenly inhale air laden with any destructive agencies producing injury immediately, or within a short period of time, such injury would be deemed to be accidental or an injury by accident. It does not seem continued the court, that the time element should be controlling. If so the courts are forced into a field of speculation in an effort to determine what standard of time shall be adopted in determining the rights of the parties.

It would not seem that the unexpected, unforeseen and therefore accidental inhalation of deleterious matter could be deprived of its accidental quality by the mere consideration of whether it took five days or five months to produce the injury.

For the reasons stated, the court concluded that McNeely's injury was compensable under the act and that he had no right to proceed at common law. It accordingly affirmed the judgment of the lower court in favor of the employer—*McNeely v. Carolina Asbestos Co. (N. C.)*, 174 S. E. 509.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Röntgen Appearance of Lung Fields in Atelectatic Bronchiectasis—Overholt illustrates, by reporting three cases, that evidence of bronchiectasis affecting the left lower lobe may be seen in the plain roentgenogram as secondary effects produced in the upper lobes. These secondary effects are revealed in the plain roentgenogram as a difference in density of the lung fields (indicating distention of the upper lobe on the affected side) and as an inequality in the position of the diaphragm best seen in the lateral roentgenogram. When such changes are seen in the ordinary postero-anterior and lateral views, by inference an atelectatic bronchiectasis of the lower

lobe should be suspected. It is not always necessary, therefore, to visualize an involved lobe behind the heart shadow. Undoubtedly there are many similar cases, in sanatoriums and elsewhere, which present cough, expectoration, occasional hemoptysis, negative sputum and roentgenograms that are inconclusive. A close study of the plain roentgenogram may reveal changes indicative of a shrunken bronchiectatic lobe behind the shadow of the heart. The investigation then can be supplemented by bronchoscopy and bronchography to confirm the diagnosis.

When Artificial Pneumothorax Should Be Discontinued—In an endeavor to state when pneumothorax should be discontinued, Dufault and Laroche review the situation and summarize its status. 1 Abandonment of pneumothorax is advocated first of all to prevent the permanent loss of function that might result from a long standing state of collapse. This argument does not stand after a moment of reflection. The healthy areas remain practically unchanged and readily resume their function whenever allowed to unfold, regardless of the duration of their immobilization. Their elasticity has not been impaired. The diseased tissues alone are incapable of reexpansion, provided sufficient proliferative organization has taken place. 2 The inconvenience to the patient becomes pressing when he contemplates leaving the sanatorium. Where shall he have his refills? 3 Unless the refills are obtained from a state or county sanatorium or from a free clinic they are somewhat costly, and the prospect of continuing them for several years is not a cheerful one to the patient of moderate or small means. This can always be arranged somehow. It should not be forgotten that the cost of illness and invalidism is still a greater burden to the patient or to his community than that of treatment. One or the other has to pay. 4 The danger of embolism, of pleural shock or of infection must be mentioned. The eventualities in store for the reexpanded lung are considered. Complete excision of the pathologic process, were it possible, would be the ideal solution. In the meantime, the best that can be done is to keep the diseased areas under control by artificial collapse and to make such a collapse as complete, as effective and as lasting as possible. Fibrotic bands and calcified nodules, which are the final stages of healing throughout the necrotic areas, are only walling in the bacilli and, at their best, can be nothing but scars, of no use whatever to the function of ventilation. Their untimely release is fraught with danger. This feeling is being implicitly expressed every time a phrenic exeresis or thoracoplasty is performed with the view of adding to the duration of a pneumothorax. 5 The condition of the lung before collapse is one of the deciding factors when reexpansion is considered. An objection often raised to the establishment of pneumothorax in early lesions is that it should be kept in reserve in case of future breakdowns. The authors advocate the institution of a collapse from the beginning and suggest its continuance until one feels satisfied that complete absorption has taken place. In simple exudations and recent infiltrations without visible cavities the leading authorities seem to agree that from two to three years of collapse counting from the time the sputum turned negative, should be sufficient. This is the minimal duration of pneumothorax, with the exception of bilateral cases, when the question is altogether different. It is granted that durable results have been obtained in a shorter time but their percentage is relatively small. In the case of an older, fibrocaseous lesion, with thick walled cavities, a minimum of from five to seven years is required. That period is not arbitrarily set. It is based on the slow process of healing in tuberculosis. It is also substantiated by surveys of reexpanded cases followed from two to ten years.

Giant Saccular Bulla of Lung—Haymaker and Karan report a case of a giant bulla projecting beyond the limits of the lung in the form of a sac. It is part of the picture of compensatory emphysema complicating pulmonary tuberculo-fibroid disease. There is presumptive evidence that an interlobar fibrous pleural band was in a large measure instrumental in causing the bulla to attain such a large size. They describe the mechanical effect of such a fibrous band on an early bulla in the contralateral lung in detail to illustrate the development that presumably took place in the incipient stage of the giant bulla.

- *Use of Maize Oil (Unsaturated Fatty Acids) in Treatment of Eczema Preliminary Report T Cornbleet with collaboration of E R Pace Chicago —p 224

Acrodermatitis Chronica Atrophicans—Sweitzer and Laymon call attention to some of the more unusual features of acrodermatitis chronica atrophicans and present five illustrative cases. One case showed almost universal atrophy of the skin with fibrous nodules, arthritis deformans atrophy of bone ulnar bands scleroderma-like changes with ulceration and extensive atrophy of the mucous membranes of the tongue, mouth and vagina. This involvement of the mucosa was most unusual. In another case, both diffuse and macular atrophy with ballooning were present. Two cases well illustrated the scleroderma-like changes, one of them being further complicated by ulceration. The last case demonstrated the odd association of acrodermatitis chronica atrophicans with lichen planus. The authors conclude that acrodermatitis chronica atrophicans is a chronic progressive disease that begins with inflammation and infiltration goes on to atrophy and is often complicated by degeneration or hypertrophic changes well exemplified in this series of cases. They were unable to determine any etiologic factor and, as has been the common experience in the past, therapy is of no avail.

New Immunologic Reaction for Diagnosis of Lymphogranuloma Inguinale—Reiss shows that the serum of patients with lymphogranuloma inguinale has antigenic properties. He submits a new immunologic reaction for the diagnosis of lymphogranuloma inguinale based on the antigenic properties of such serum. The absence of antibodies in the serum is evident, because, when the serum is combined with the Frei antigen, instead of neutralization he has observed an increase in the reaction. Blood was taken in clinically typical cases verified by a positive Frei reaction. The serum was separated mixed with a 0.5 per cent solution of phenol and kept in the icebox. Before the test was attempted, the serum was proved to be sterile culturally. The author performed the experiment in six cases, with uniform results. Tests were made with the following preparations: (1) for the control a 0.5 per cent solution of phenol in physiologic solution of sodium chloride; (2) the Frei antigen; (3) a mixture of 0.05 cc of Frei antigen with 0.05 cc. of blood serum from a patient with lymphogranuloma inguinale (injected intradermally) and (4) 0.1 cc of blood serum from a patient with lymphogranuloma inguinale (injected intradermally).

Maize Oil in Treatment of Eczema—Cornbleet treated eighty-seven cases of eczema with maize oil with gratifying results. A few of the patients had asthma and this was benefited in some as well as the eczema. The improvement seems permanent, and there have been few relapses in the four and a half years since the treatment has been used. A number of patients who had had eczema since infancy have remained well for as long as three years. By eczema is meant the condition generally referred to as allergic eczema exudative and diathetic eczema, Besnier's prurigo or generalized neurodermatitis. In most of the author's patients the condition commenced in infancy and continued indefinitely with alternating exacerbations and relatively quiescent intervals during which the skin at the usual sites was thickened scaly and pigmented. The patients were more than 5 years of age and for the most part were adolescent boys and girls and young adults. Before the use of the oil was commenced, it was ascertained that the patient would not recover easily or at least not on standard therapy. In a few cases local adjuvant measures were used to relieve itching.

The average time necessary to achieve a clinical cure is from twelve to eighteen months. The maize oil was given orally. The patient began taking one tablespoonful before or after meals, whenever he tolerated it best. The dose was increased gradually until four tablespoonfuls was taken three times a day. The author used an especially refined maize oil which is less disagreeable to the taste and is tolerated better than that bought in the open market. The oil when taken slightly chilled is more palatable.

Calcium Content of Cerebrospinal Fluid, Blood Serum and Serum Ultrafiltrate—Michaels and Searle compared the calcium content of the blood and the cerebrospinal fluid with that of an ultrafiltrate of the serum. Their series, in which these three determinations were made simultaneously, consists of eighty cases in which eighteen various neuropsychiatric diagnoses were made. In conditions of nervous instability various somatic and neurologic deviations vasomotor instability and retinal endarteritis, the calcium observations were not different from those in cases that did not present these conditions. The constitutional type (asthenic, athletic or pyknic), weight-height index, sex, age, blood pressure and intelligence quotient could not be correlated. The ratios of diffused to non diffused calcium and the permeability quotients were within normal limits. It seems strongly indicated that one obtain blood and spinal fluids simultaneously and study the interrelationship of the calcium partitions with the values for other substances in these fluids especially the amounts of inorganic phosphates and other inorganic elements and of proteins and, above all, the potassium-calcium ratios. The intensive study of fewer cases with repeated studies of individual cases to ascertain normal fluctuations, especially when the clinical manifestations may be evanescent and transitory, is desirable. Prolonged persistent studies throughout the various phases of an illness as it occurs in the evolution of a psychosis, especially in epilepsy, are also necessary. A multidimensional point of view implying knowledge of the integration and intricate intercorrelations and interdependence of all the levels of the personality is essential for any valuable contribution in the realm of calcium metabolism in patients with neuropsychiatric disorders.

Effect on Thujone Convulsions of Insulin and of Variations in Water Content of Brain—Keith observed that the administration of large amounts of water by stomach tube, accompanied by repeated subcutaneous injections of pitressin, causes spontaneous convulsions in rabbits with an increase in the water content of the brain and makes them much more susceptible to thujone convulsions. Pitressin alone given in repeated subcutaneous injections does not increase the water content of the brain but does increase to a slight extent the animal's susceptibility to thujone convulsions. Distilled water given by stomach tube in large amounts increases, to some

extent, the susceptibility of the rabbit to thujone convulsions and, to a considerable extent the water content of the brain. The production of a maximal increase in the water content of the rabbit's brain by means of intravenous injection of hypotonic solution of sodium chloride does not increase the animal's susceptibility to thujone convulsions. The production of insulin hypoglycemia to the point at which spontaneous convulsions occur makes rabbits more susceptible to thujone convulsions and there is some increase in the water content of the brain accompanying this procedure. Hypoglycemic convulsions and convulsions produced by the administration of water or water and pitressin do not inhibit the convulsant action of thujone. Whatever the factor may be that increases the animal's susceptibility to convulsions it is evidently not the increase in the water content of the brain.

Polycythemia Vera and Nervous Manifestations—

Adams reports nine cases of polycythemia vera, in six of which medical advice was sought for symptoms referable to the nervous system (headache, dizziness and paresthesia). The length of time under observation varied from six months to eleven years. In one case a cerebral decompression was performed for a suspected brain tumor. The differential diagnosis was difficult because of the presence of a preceding injury to the skull. The three cases in which there were abdominal complaints also offered diagnostic difficulties as evidenced by fruitless surgical procedures. The average age of onset of symptoms in eight cases was fifty years. In one case in addition to ascites an extensive recurring hydrothorax was present. Three patients had an associated hypertension at the time the polycythemia was recognized. It is impossible in each instance to state which condition occurred first. Two patients observed over a long period of time in the hospital, received treatment which reduced the red blood count, resulting in marked symptomatic improvement, but failed to lower the blood pressure. In all three cases the heart was found to be normal in size. Splenomegaly was present in every case which with the blood picture formed the criteria for diagnosis. In addition the liver was palpable in all except one. The tendency to bleed was exemplified by its occurrence in all cases except one. Every patient subjected to surgical procedures suffered from post-operative hemorrhage. Therefore every known or suspected case of polycythemia should be admitted to the hospital prior to an operation of any kind including tooth extractions. Treatment consisted in the use of phenylhydrazine hydrochloride and roentgen irradiation. Roentgen therapy in repeated small doses over the long bones, as recommended by Pack and Craver, has been the method of choice in recent years.

Observations Following Administration of Tetanus Toxoid—Sneath and Kerslake state that the demonstration of residual amounts of tetanus antitoxin in the blood serums of twenty-five out of twenty-seven adults a year after the injection

of three doses of tetanus toxoid is of distinct value as an indication of the persistence of this antitoxin induced by active immunization. There is definite evidence that a secondary stimulus with tetanus toxoid induces not only the rapid development of tetanus antitoxin in man but also an enhancement of antitoxin titer within a week, on an average of about twenty times that of the residual amounts found a year after three doses of toxoid. Since three days after the prophylactic injection of 1500 American units of tetanus antitoxin the blood serum of man has been shown to contain from 0.1 to 0.25 unit per cubic centimeter, it is evident that within a week of the secondary stimulus thirteen persons of a group of fourteen developed at least the equivalent of that afforded by a prophylactic dose of antitoxin. The serum titer of the same persons continued after a month to show antitoxin at levels sufficient to retain this degree of protection. Although one of the group failed to develop antitoxin to this level, there is no doubt that it was possible in this instance to induce the early development of a measurable amount of antitoxin as a result of a secondary stimulus, whereas it was not possible to show that such followed the first series of toxoid injections.

Comparison of Presumptive Test Media for *Coli* Aerogenes Group of Bacteria—Shunk tested pure culture strains of *Escherichia Aerobacter* and *Citrobacter* from thirty subjects 201 strains in all for gas formation in plain lactose broth brilliant green lactose peptone bile, crystal violet buffered broth and fuchsin broth. When small inoculums were used (less than fifty organisms per tube) lactose broth and brilliant green lactose peptone bile gave positive tests after twenty-four hours of incubation at 37 C for all the 201 strains. In crystal violet broth after forty-eight hours of incubation with similar small inoculums only 49 per cent of these strains gave positive tests. From only five persons of the thirty did all strains produce as much as 10 per cent of gas in forty-eight hours, and all strains from five others failed to form gas in the same period of incubation. Few strains formed gas in fuchsin broth when small inoculums were used and with relatively large inoculums only thirty-three of the 201 strains formed gas in forty eight hours. When small inoculums of a dye sensitive strain of *Escherichia* were added to the crystal violet broth and the tubes were also inoculated with a loop of a culture of a greenish fluorescent water organism, the fluorescent bacterium so modified the medium that this strain was able to produce gas in forty eight hours or less. Fewer failures to get gas formation in the presence of *Escherichia-Aerobacter* organisms in water samples are to be expected than the poor showing of this medium when tested by pure culture strains would indicate.

Viosterol in Pathogenesis of Rickets Due to Beryllium.—Sobel and his associates made comparative observations of in vitro calcifications of bones obtained from rats with beryllium and calcium rickets. They found that there was a marked diminution in the calcifying power of bones of animals suffering from beryllium rickets. The bones of rats receiving viosterol in addition to a beryllium rickets-producing diet showed similar diminution of in vitro calcifying ability. Although the administration of viosterol failed to prevent the development of rickets in rats receiving beryllium, it nevertheless resulted in a rise of the calcium-phosphorus product in the serum.

Specificity of Streptococci Isolated in Studies of Diseases of Nervous System.—The absence of streptococci in cultures of the brain and in sixty-two rabbits that had been given injections of sterile filtrates or dead streptococci makes it clear that the streptococci isolated by Rosenow from rabbits that had been given injections of living streptococci were not secondary contaminants from the air or elsewhere. The characteristic cataporetic time and velocity and virulence, and specific serologic properties also prove their identity. In the case of persistent sneezing, the striking similarity between the symptoms obtained in animals and those of the patient were not limited to reproduction of the chief symptom persistent sneezing but included important concomitant symptoms, such as attacks of great restlessness and stormy respirations expiratory grunting mucous rattle in the throat and alternation of periods of abnormal excitation with periods of moderate drowsiness or marked lethargy. In no instance were these results obtained under like conditions with streptococci derived from patients who were used as controls, or with streptococci derived from the patient with persistent sneezing some time after

recovery, or with this streptococcus after aerobic cultivation, or in a long series of similar experiments with streptococci derived from patients with other diseases. Only a few animals that received injections of streptococci in a study of a series of cases of respiratory arrhythmia were seen to sneeze. The degree and duration of symptoms following injection, especially of the heat-killed organisms and filtrates of active cultures, were quantitatively roughly proportional to the dose injected. The impulse of sneezing was of central origin and was apparently due to lesions resembling those of encephalitis chiefly in the medulla surrounding the fourth ventricle. The active principle was soluble in ether and was destroyed by boiling. The principle was retained through as high as thirty-nine rapidly repeated subcultures in dextrose-brain broth, through four successive animal passages, and for thirty days at 35 C. on sealed blood-agar slants. It was lost after several aerobic blood-agar platings. These facts, and the fact that no other cases occurred, suggest that the "sneeze-producing" principle and other specific features of this streptococcus represented acquired properties of streptococci normally present in the throat and that these properties were subsequently lost in the throat of the patient as in the test tube.

Cortical Autonomic Epilepsy.—Watts and Frazier point out that recent studies on autonomic representation in the cortex point to an explanation of the long recognized visceral symptoms and signs associated with focal seizures and occurring as an aura or independently. Nausea and vomiting of increased intracranial pressure are, of course, not of localizing importance. However, in focal epilepsy, especially in the absence of increased intracranial pressure, visceral phenomena may assume some significance. As illustrations of these visceral phenomena the authors discuss two cases in which manifestations such as nausea, epigastric distress and vomiting presumably aborted or were substituted for epileptic convulsions. They postulate that the neuronic discharge sometimes manifested itself through the gastro-intestinal musculature and sometimes through the skeletal musculature. In the first case nausea followed by vomiting aborted individual epileptic convulsions. In the other case several focal convulsions occurred, followed by an interval of four years in which there were periodic attacks of nausea and vomiting but no convulsions. After four years the characteristic convulsive seizures were resumed. Nausea and vomiting may be considered the result of neuronic discharge from the motor autonomic portion of the cerebral cortex. Epigastric auras and other abdominal sensations usually are not so called referred sensations but probably arise from vigorous and perhaps abnormal movements of the gastro-intestinal tract. Insufficient work has been done to know what part of the human cortex contains autonomic representation.

Superdiathermy in Treatment of Dementia Paralytica.—Cullins and his associates employed hyperpyrexia extensively in the treatment of patients suffering from dementia paralytica, whenever it was thought that the patient would cooperate to any degree. Since 1932, seventy-eight parietic patients have been given malarial therapy. No deaths have followed this form of treatment. Their conclusions are that malarial inoculations are the treatment of choice in all cases of dementia paralytica in which barring contraindications it is possible to administer this type of therapy. When a patient is encountered who will be unable to withstand the rigors of an illness such as

malaria superdiathermy may be instituted. In the last three years 205 patients have been treated with superdiathermy requiring 1,771 treatments. Discontinuance was necessary in only eight cases because of slight burns and in twenty-nine others in which cyanosis, rapid heart action or general restlessness developed. Diathermy was not administered more than twice a year to any patient. A course of ten treatments was arbitrarily instituted and was followed throughout the series. An attempt was made to maintain a total of sixty hours of fever with a temperature ranging from 104 to 106° throughout the course. The temperature can be reduced by opening the covers from the feet and legs and from round the neck. If necessary the patient's feet and legs can be cooled by the application of towels and cool water. After the temperature has decreased to the desired point the feet and legs may be covered again and the temperature allowed to remain at the desired level. A comparatively large number of patients derived considerable benefit from this form of therapy in that the majority of them showed unmistakable evidences of improvement characterized by changes in weight behavior, blood and spinal fluid. The period of life expectancy has been prolonged in a number of these patients and they have generally improved otherwise. It is difficult to state the exact therapeutic agent that was instrumental in bringing about the improvement because the majority of the patients had been treated before they arrived at the hospital. A certain number had been treated by malaria others had been treated by diathermy and others by a combination of antisyphilitic remedies. There are many reasons for the belief that superdiathermy has its place in the treatment of neurosyphilitic patients and that malaria and chemotherapy also have their advantages and disadvantages. There seems to be little doubt as to the efficacy of malaria, and undoubtedly the administration of this form of therapy is of paramount importance, while superdiathermy probably occupies a place second only to malaria.

Diaphragmatic Hernia at Esophageal Hiatus, the Short Esophagus and Thoracic Stomach—Truesdale presents the fourth case of hiatus hernia of the diaphragm treated surgically by a thoracic approach which has resulted in partial relief of symptoms and cannot be termed a cure. A comparative study of his specimens with illustrations in the works of other investigators prompts him to offer a new theory as to the origin of congenital short esophagus and thoracic stomach. 1 The enlarged esophageal hiatus or any other congenital aperture in the diaphragm occurs as a result of embryologic failure of fusion. 2 Almost invariably, thoracic stomach is the result of herniation through a congenital hiatus hernia and may occur at any time after birth. 3 The short esophagus is the result of cessation of traction on it by the stomach which has assumed a position in the thorax. In many instances a short esophagus of a few centimeters is the result of inflammatory changes at its lower end. Reasonably accurate deductions as to the posi-

tion of the stomach and the length of the esophagus can be made only by careful observation at the operating table or at necropsy.

Comparison of Yeast Milk and Irradiated Milk in Treatment of Infantile Rickets—Wyman and his co workers selected six infants having active rickets, who on admission to the hospital were placed in a separate ward and during a preliminary period were given a simple calory adequate diet, without antirachitic supplement, to make certain that healing was not taking place, after which the milk in the diet of three infants was replaced by irradiated milk and that of the other three infants was replaced by yeast milk. During the test period roentgenograms and blood analyses were made frequently. The six infants showed healing within four weeks when fed from 26 to 32 ounces of vitamin D milk daily, irrespective of whether it was irradiated milk of 50 units or yeast-fed cow's milk of from 60 to 65 units per quart. Roentgenologically there is no obvious difference in the clinical antirachitic value of the two types of milk. All the cases showed a calcium phosphorus product of less than 40 when the vitamin milk was first administered. The progressive increase of this product throughout the duration of the test is indicated. The general trend of the curves is substantially the same for all groups. If the rate of increase of the serum calcium phosphorus product is an index of the rate of recovery from rickets, there is nothing to choose between the rates of recovery on the two kinds of milk used.

Tannic Acid Silver Nitrate Treatment of Burns—Bettman submits an improvement on the tannic acid method of treating burns. The method consists in the use of a 5 per cent solution of tannic acid followed by a 10 per cent solution of silver nitrate. He states that far better results are obtained and lists the following advantages: 1 The saving of lives that would be lost through the slower method of tanning. 2 The immediate stopping of the loss of body fluids, thereby preventing the consequent concentration of the blood. 3 The immediate prevention or very definite minimizing of shock. 4 The immediate prevention of the absorption of toxic products. 5 The prevention of infection by the short period of application of moisture and the early drying of the tanned tissues. 6 The saving of the kidneys and other organs from the effects of fluid concentration and the absorption of toxins and infection. 7 The greater comfort of the patient. 8 Safe carrying of the patient past the first twenty-four hours, which is the most critical period following a serious burn. 9 Avoidance of the second critical period, that of infection and late absorption of toxic products. 10 The simplification of the nursing problem, especially in the first twenty-four hours. 11 The prevention of further breaking down of tissues, which results from long application of wet dressings. 12 The prevention of chilling, which also results from the long application of cold, wet dressings. 13 The formation of a thin, flexible coagulum. 14 The speedy healing of the burned areas with a shortened period of hospitalization. 15 The prevention or minimizing of heavy contracting scars by early, rapid healing in the absence of infection. 16 The lessening of the amount of skin grafting and secondary corrective surgery necessary. The author has treated twenty-one cases with gratifying results except in the case of a man of 77 who had an 80 per cent burn and who died ten hours after the accident.

Blood-Cerebrospinal Fluid Barrier—Masserman gave twenty-eight parietic and twenty-two schizophrenic patients 0.01 Gm of sodium bromide by mouth per pound of body weight three times a day for five days, after which the bromide content of the blood, spinal fluid and cisternal fluid was determined. Analysis (by the method of Walter) of the data showed that the mean bromide contents of both the lumbar and the cisternal fluid of the parietic group exceeded those of the schizophrenic group by 3.64 ± 0.0983 and 3.29 ± 0.604 mg per hundred cubic centimeters indicating a significantly lowered blood-cerebrospinal fluid barrier permeability to bromides in dementia paralytica as contrasted with schizophrenia. That the barrier permeability in dementia paralytica is lower than normal whereas in schizophrenia it is abnormally high is indicated by contrasting the blood cerebrospinal fluid ratios of both psychotic groups with those of a group of normals reported by Malamud. The latter comparisons may not be determinative because of the possibly different technic employed.

Recurrent Rheumatic Fever with Pericarditis Terminating in Septicemia.—Yater and Hedley cite a case in which attacks of rheumatic fever recurred for a year and a half and were alleviated by salicylate therapy and in one of which there was pericarditis with effusion. During one of these attacks of polyarthritis, manifestations of septicemia developed suddenly which did not respond to salicylates. Blood cultures showed flourishing growths of alpha prime streptococci. At necropsy there was evidence of healed pericarditis and a purulent peritoneal effusion of unexplained origin. Experimental bacteriologic studies with monkeys and rabbits showed that the organism isolated from the patient's blood was extremely virulent and produced in many of the animals arthritis and ulcerative vegetative endocarditis. The relationship to rheumatic fever of streptococci in the general circulation or infected tissues is still a question. Many of the earlier workers occasionally obtained streptococci on blood culture or on culture of joint fluids. These were hailed as possible etiologic agents. In no instances have these claims been substantiated.

- *Psoriasisform Carcinoma of Skin L. Savatard—p 51
- Eczema J T Ingram—p 64

Psoriasisform Carcinoma of Skin—In 1930 Savatard suggested that intra-epidermal carcinomas of the skin differed only from the more usual carcinomas of epidermal origin in that their intra-epidermal growth was prolonged and that, though they may at some period proliferate within the cutis with tumor formation, they may never do so or they may atrophy in part or in whole, that the ordinary epithelioma also originates intra epidermally, but proliferation within the cutis with tumor formation so rapidly supervenes that its intra epidermal spread is obliterated, yet if examined at an early stage lateral intra epidermal spread, as well as downward proliferation within the cutis, can be appreciated, though the intra epidermal spread is not characterized by the same morphologic cellular change as is the case in these chronic superficial lesions. He also indicated that unless the fact that these superficial, apparently benign lesions are carcinomas confined for the most part within the epidermis, and not precarcinomas, was recognized, a true conception of the pathogenesis of carcinoma of the skin would not prevail. Having observed several new cases he concludes that: 1 The psoriasisform carcinoma is a chronic superficial carcinoma of the skin. 2 It may be either intra-epidermal or intra epithelial. In the former the neoplasia affects the epidermis alone, while in the latter the epidermal disturbance is associated with a similar hyperplasia within the sweat ducts and glands. 3 Paget's disease of the nipple is usually an intra-epithelial carcinoma affecting the mammary ducts as well as the skin round the nipple, but it may be a purely intra epidermal carcinoma without lesions of the duct. 4 "Extramammary" Paget's disease is usually an intra epidermal carcinoma, though in the rarer cases, when sweat ducts and glands are involved, it must be considered as being intra-epithelial. Such cases correspond to the usual mammary type. 5 Histologic evidence indicates that the psoriasisform carcinoma spreads not by permeation of tumor cells into the surrounding healthy epidermis but by what may be termed a "cancerous metaplasia" of adjacent normal cells.

Intracorneal Injections of Mercuric Cyanide in Trachomatous Pannus—Shalom treated twenty-five cases of severe pannus rebellious to previous treatment by intracorneal injections of mercuric cyanide. Under local anesthesia of a 1 per cent solution of pantocain an eye speculum is introduced and a 1 cc record syringe containing 0.5 cc of 1:1,000 mercuric cyanide is fitted with a very fine needle. The patient is asked to look downward, and with the eye of the needle turned toward the cornea the needle is introduced tangentially into the corneal substance about 1 mm. from the limbus, usually in the upper part of the cornea where the pannus is thickest. A few drops of the solution are injected slowly. The cornea at once assumes a grayish opaque color which spreads from the upper part of the cornea downward, the extent depending on the amount of solution injected. The needle is withdrawn, the speculum is removed and the eye may be left open or bandaged. The whole procedure is painless. The twenty-five patients operated on continued receiving daily local treatment in the outpatient dispensaries. Two months later five showed a recur

rence of the pannus in a much milder form. They received intracorneal injections again and when examined four months later showed microscopically clear corners. In three cases although the pannus infiltration had disappeared two months after the operation fine blood vessels could still be seen running in the corner. Ten cases examined by the slit lamp showed that the pannus had decreased quantitatively and qualitatively but tractionous vascularization was still present in all.

Transitory Reduplication of Second Tricuspid Sound as Sole Sign of Coronary Thrombosis J H Williams—p. 147

Treatment of Malignant Disease in Upper Jaw—Harmer states that the combination of surgery, diathermy and irradiation marks the great advance that has been made in the treatment of malignant disease of the upper jaw. A large percentage of his cases (110) have been advanced some of them hopeless, so that treatment was given merely for palliation, and yet nearly a third of the carcinoma patients are living, two for two years five for three years one for four years and six for five years or more. Half the sarcoma patients are alive, and those who survive for more than one year usually remain free from disease for long periods, and although only two of the endothelioma patients are now living four others survived for more than three years.

Clinical Use of Progesterin—Bishop and his associates indicate the underlying principles by which they have been guided in their use of progesterin. After a consideration of the interrelations of the pituitary, ovary and uterus they suggest the use of progesterin in 1 Habitual abortion the injection of 1 rabbit unit daily for two months commencing a month before the usual time of abortion. 2 Threatened abortion steps should be taken to determine, as far as possible whether the fetus is still alive, and then 1 rabbit unit of progesterin should be administered daily until signs of threatened abortion have disappeared. 3 Functional menorrhagia, progesterin should be given in combination with anterior pituitary extracts. The anterior pituitary factor should be administered continuously by injections of up to 500 rat units three times a week in the course of two months. The course may be repeated after an interval of a month or two. In the premenstrual phase and during the actual time of the bleeding the anterior pituitary extract should be given daily, together with 1 rabbit unit of progesterin. 4 Dysmenorrhea 1 rabbit unit of progesterin should be given daily, commencing as soon as the pain appears or a day or two before if possible and continuing until the period ceases. 5 Uterine hypoplasia scanty infrequent menses and amenorrhea, the result of treatment in these cases can best be evaluated by measuring the length of the uterus with a sound. Treatment should consist of 250,000 international units of estrogenic substance (in the form of dihydro estrin benzoate) injected on the first, fourth, eighth, eleventh and fifteenth days of the course a total of two and one-half million units being given. On the nineteenth, twentieth, twenty-first, twenty-second and twenty-third days 1 rabbit unit of progesterin is administered. Menstrual bleeding commences on any day up to ten days after the last injection of progesterin. This course should be repeated once, and about a fortnight later the length of the uterus should be measured again. The authors have been concerned solely with the endocrine causes of these cases of functional disorders of menstruation and pregnancy but they

point out that other predisposing factors should not be neglected in treating these patients. The three most important considerations are the necessity for excluding organic lesions of the pelvic organs, the difficulty of obtaining an accurate and reasonable history and of assessing subjective symptoms, and the difficulty of determining the degree of psychologic disturbance.

Transitory Reduplication of Second Tricuspid Sound—Williams reports a case of coronary thrombosis of the T₁ type in which a striking reduplication of the tricuspid second sound occurred for four days after the closure. This was the only sign of cardiac abnormality, as the history of the coronary attack was not obtained until after electrocardiographic diagnosis had been made, owing to the patient's apprehension. As a result of this apprehension and the otherwise normal observations on examination of the heart, the patient might reasonably have been dismissed as having no abnormal condition and allowed to return to ordinary work probably with disastrous results. The view is put forward that a transitory reduplication of the tricuspid second sound is highly suggestive of coronary thrombosis and that any patient showing this sign after a fainting attack should be submitted to expert electrocardiographic examination before being allowed to return to his usual duties.

Xerophthalmia and Its Treatment—In cases of xerophthalmia in which the cornea was involved and in which the prognosis seemed particularly bad and little or no improvement could be seen in spite of lengthy treatment, de Villiers performed a central tarsorrhaphy in addition to the cod liver oil treatment. It seemed a logical operation to do to (1) reduce the exposure of the eye, (2) increase the temperature of the cornea, (3) increase the humidity of the corneal surface and eliminate the desiccating influence of the air and (4) reduce the exposure of the eye to the bright light in short to increase the vitality of the affected cornea. The number of cases in which it was done from a statistical point of view was negligible, but the results were sufficiently good to encourage the author to recommend the operation in cases of xerophthalmia in which the cornea is involved, as an addition to the usual treatment. The adhesion can be divided at any time later and the lids function again in the normal manner.

Dye Test for Examination of Renal Function—

Jasienksi discusses several dyes in relation to their reflection of the functional condition of the kidneys. Indigo carmine is not retained in the body, is not decomposed and does not lose its coloring qualities. It is eliminated in the urine without change and almost quantitatively. Several conclusions may thus be drawn from the use of this dye in estimations of renal function. The most important of these is when the renal disorder is unilateral, in which case it may be concluded that the elimination of the dye is normal or that it is slower or weaker than that of the opposite kidney, or that it is completely absent. Trypan red is a colloidal dye that does not pass through a membranous filter and is not eliminated by the bile or normal kidney. Introduced into the circulation, it remains for a long time in the organism. Introduced into the circulation immediately before cystoscopy, it is a means of determining whether both kidneys eliminate albumin or whether this elimination is confined to one kidney. The author believes that the qualities of the two dyes when combined clarify an unusually large number of facts concerning renal function. If the kidney eliminates only indigo carmine, it is really healthy. If it is permeable to both dyes, it is diseased. If the elimination is limited to trypan red, the renal parenchyma is seriously damaged. Finally, if no dye is eliminated, some structural abnormality or blockage is the probable explanation.

Action of Cortical Extracts on Urea Retention—

Gomez injected from 3 to 4 cc of a fresh extract of renal cortex intramuscularly or subcutaneously into thirty-seven patients. The injections were repeated daily for from five to seven days. The patients had an elevated level of blood urea and showed other evidences of renal insufficiency such as nocturnal pollakiuria and albuminuric retinitis. All had arterial hypertension. They were observed for a considerable period previous to the initiation of therapy and, if they required a low protein diet, they were watched until after stabilization of the humoral state. In twenty-four of thirty-five patients there was a true decrease in blood urea from twenty-four to forty-eight hours after the end of treatment. In eight patients there was no change and in three there was a slight increase of blood urea. In the eight or ten days following there remained a diminished urea level in twenty-six of thirty-three patients. In seven cases the urea remained at the same level as before treatment. A month or six weeks later there was a decrease in fourteen of the fifteen patients followed. In one there was an increase. Between the second and fifth months, only eight cases were studied. In four the urea remained lowered and in four it had returned to the earlier level. Subjectively, improvement was the rule.

*Primary Perithelioma of Liver Case G Selvaggi —p 116

Primary Perithelioma of Liver—Selvaggi regards perithelioma as a variety of malignant mesenchymal tumor with histologic, morphologic and clinical characteristics that permit its differentiation from the other forms of mesenchymal tumors. Primary perithelioma or sarcoma of the liver is rare. It can be differentiated from primary cancer of the liver by its objective data. The liver is greatly enlarged and has a nodular nongranular surface. There is neither ascites nor jaundice. The

fever is continuous and high, the urine is free of biliary pigments, the evolution of the condition is rapid and acute, and the condition is exceptional in the aged. Primary cancer, on the contrary, gives the following data. The liver is normal, nodular, granulous and cirrhotic, ascites and jaundice are frequent and intense, there is slight or no fever, the urine contains abundant biliary pigments, evolution is slower than in sarcoma, and the condition is exceptional in youth but common in old age. The prognosis of perithelioma of the liver is fatal. Up to the present, both medical and surgical treatment have proved unsatisfactory. Roentgen treatment is harmless and gives good results as a palliative treatment.

Cystic Spinal Arachnitis—Soto Romay says that cystic spinal arachnitis is frequent. The disease does not constitute an anatomoclinical entity among other clinical processes resulting in medulloradicular compression. The varied symptoms and the conflicting results of the investigations are the characteristics for a diagnosis of presumption, especially if either trauma or tuberculosis, the most frequent etiologic factors of the disease, exists in the history of the patient. In cases in which cystic spinal arachnitis is suspected to be the cause of any medulloradicular compression, early operation is indicated. The meningeal involvement is secondary to the radicular lesion and may be avoided by an early operation. The surgical treatment aims at reestablishing the communication of the subarachnoidal space, which is important for the protection of the neuraxis and should be followed by medical treatment to control the etiologic factor causing the disease.

Head's Zones in Pulmonary Tuberculosis Marie von Babarczy —p 33.

Endogenic Reinfection in Pulmonary Tuberculosis—Eltze describes a case of active pulmonary tuberculosis, which is probably the result of an endogenic reinfection of an old calcified primary focus. The activity of the old primary complex was indicated by the increased sedimentation speed of the erythrocytes before other symptoms became manifest. The author points out that the transmission of a tuberculous inflammation from the primary complex to the pulmonary tissue is a rather frequent occurrence in children but not in adults, although the calcified primary focus has connections with the organism by way of the lymph stream. The interlobar space adjacent to the primary focus became involved, as a tuberculous exudate developed. Interlobar adhesions are frequently observable in roentgenograms. They are not necessarily the result of tuberculosis, but whenever they are found tuberculosis should be thought of. Whether in addition there were primary tuberculous foci in the apical regions, which could not be observed, cannot be definitely decided. The observation that in adults a new tuberculous process may develop outside the apical region, near an old, calcified, primary focus, and in the absence of an infraclavicular infiltrate is an important observation. It is difficult to decide whether the tuberculous pulmonary process should be considered an endogenic or an exogenic reinfection. Nevertheless, the fact that the process developed near the old primary focus makes an endogenic reinfection from an old primary focus seem most probable.

Pleocytosis in Cerebrospinal Fluid in Cerebral Tumors

—Rothfeld maintains that the condition of the cerebrospinal fluid may vary greatly in patients with cerebral tumors. In some instances the fluid is entirely normal while in others the number of cells, the protein content and the colloid reactions may undergo changes. A number of authors consider a normal cerebrospinal fluid or a slight lymphocytosis characteristic for cerebral tumor. However in recent years attention has been called to cases with pleocytosis. A case of severe lymphocytosis reported by Scharpf is especially noteworthy because the histologic examination of the tumor disclosed necrotic foci with disintegrating cells. The author observed a number of cases of cerebral tumor in which the pleocytosis gave difficulties in the differentiation of suppurating meningitis from cerebral abscess. In order to determine whether the pleocytosis in the course of a cerebral tumor is actually due to inflammatory manifestations or to disintegration of the tumor or to its localization the author decided to compare the cases of pleocytosis with those in which the cerebrospinal fluid was normal. On the basis of the aspects of the cerebrospinal fluid he was able to differentiate three groups. The first group comprised cases of pleocytosis, with positive protein and positive colloidal gold reactions, some of these patients had cerebral tumors and in others the tumor was in the posterior cranial fossa. The patients belonging to the second group had normal cerebrospinal fluid. In the third group the cerebrospinal fluid presented the compression syndrome. The author reaches the conclusion that pleocytosis in the cerebrospinal fluid of patients with cerebral tumor is not a rare occurrence, for he observed it in 27.6 per cent of the cases. He found that for the development of pleocytosis it is necessary that the tumor be in connection with the ventricular system and that it contain disintegrating and inflammatory processes. In the absence of one of these factors there is no pleocytosis, and the fluid is either normal or presents the syndrome of compression. Proliferation of the tumor into the subarachnoid space or into the meninges does not necessarily produce pleocytosis. The author concludes from this that if the cerebrospinal fluid shows a pleocytosis in the course of cerebral tumors, it may be assumed that the tumor has reached the ventricular system and contains processes of disintegration and inflammation, provided the tumor is not localized in the posterior cranial fossa. A normal cerebrospinal fluid or the compression syndrome does not permit conclusions about a relation of the tumor to the ventricular system or about processes in the tumor tissue.

Chronic Trophedema—Langsteiner and Stiefler describe three cases of noncongenital chronic trophedema. The first case was that of a youth, aged 19. In this case the trophedema involved both legs. According to the statements of the mother of the patient, the swelling appeared first on the right member when the boy was 6 months old, and on the left member six months later. Subsequently the swelling increased. In the course of the second year, and several times later, erysipelas-like symptoms developed on the lower extremities, and, following these attacks, a slight enlargement of the members became evident. In 1926 a phlegmon developed on the right leg and was surgically treated, and during the following year a suppurating fistula developed on the left knee. Healing of the wound after incision was extremely slow. The patient never complained of pain in the lower extremities, and walking was not noticeably impaired. He had a rather feminine type of hair growth and a mild degree of hypogenitalism. The other two cases observed by the authors concerned two sisters. In both, only the left of the lower extremities was involved. There was a quantitative reduction of the electrical irritability in the diseased region. The "wheal time" was shortened in

the edematous region. Tests also revealed an increased disintegration of the thyroid and the ovaries and a greatly increased disintegration of the anterior lobe of the hypophysis, factors that are indicative of an involvement of the endocrine glands. The case history of the first of the two sisters is particularly noteworthy because it demonstrates the uselessness of the various surgical interventions and shows that the wearing of suitable bandages is the most satisfactory measure. The authors review several theories on the etiology of trophedema and then mention the different types that were differentiated by Courtellemont. They state that they consider the various eponymic terms (Milroy's, Milroy-Nonne's, or Milroy-Nonne-Meige's disease) less desirable than the term "chronic trophedema." According to the particular type this term can then be further specified by adding congenital, hereditary or familial.

Culture of Tubercle Bacilli from Laryngeal Smears J Schramek and P Hegedus—p 237

Diabetic Cataract and Insulin Therapy—Braun shows that diabetic cataract is not necessarily the result of a shifting in the osmotic equilibrium between the lens and the aqueous humor of the eye, nor does he think that the acid intoxication of the organism in severe diabetes is the causal factor. He believes that other still unknown factors play a part and that the question of predisposition should be given attention. Large doses of insulin do not damage the lens. On the contrary, it has been demonstrated that under the influence of large doses of insulin advanced opacities of the lens may rapidly disappear.

Significance of Adrenals in Water Exchange—Rigler states that the osmotic pressure of the cellular contents of mammals is constant and amounts to about 8 atmospheres. Since this pressure is subject to disturbances from numerous factors, precise regulatory mechanisms are required to maintain it. The author cites observations indicating that the adrenals play an important part in this regulation. In a water tolerance test on adrenalectomized adult mice he observed an extremely limited excretion of water (only one tenth of that of the controls). He assumes the possibility of the existence of accessory adrenals in animals that survive adrenalectomy for longer periods. The exclusion of the adrenal function can evidently be partly compensated by a suitable regulation of the temperature of the moisture content of the air and of the food. In the feeding of these animals the sodium chloride intake is important. However, even these apparently normal animals show an insufficiency as soon as their osmoregulation is taxed by a water tolerance test. Symptoms develop that correspond to those of 'water intoxication' and the animals die in convulsions. The author assumes a possible analogy to eclampsia. For Addison's disease he concludes from these observations that the restricted intake of hypotonic fluids and the treatment with sodium chloride might prove effective.

Blood Ammonia Following Glycine Tolerance Test in Liver Diseases—After stressing the importance of the liver in the intermediate metabolism, particularly in the deamidization of the amino acids and in the formation of urea, Kohn and Stein report their studies on the ammonia content of the blood following intravenous administration of glycine to persons with and without diseases of the liver. By using a homogeneous amino acid, the physiologic conditions were adhered to closer than by using ammonia salts. The injection was given while the persons were fasting. As a rule, 3 Gm of glycine was dissolved in 20 cc. of distilled water, the mixture was sterilized and then injected. The first blood specimens were withdrawn five and twenty minutes after the injection.

In persons without disease of the liver, the ammonia content of the blood reached its maximum from sixty to seventy minutes after the injection. In diffuse diseases of the liver the course of the ammonia curve showed the following abnormalities: 1 In the majority of these patients, the maximum was reached much later (from 110 to 120 minutes after the injection). 2 In a second type (rather rare) the increase in the ammonia content was prompt, but the decrease was slow. 3 In a few cases in which other tests of the hepatic function had also been negative, a normal deamidization curve was noted in spite of diffuse hepatic disease. The authors admit that this method permits no differential diagnostic conclusions about the nature of the hepatic disorder.

Congo Red in Pernicious Anemia—The accidental observation that the blood status of a patient with pernicious anemia improved following the injection of congo red induced Massa and Zolezzi to try this treatment. They employed a 0.5 per cent solution of congo red in a 0.5 per cent solution of sodium chloride prepared in the following manner: Three Gm. of congo red was placed in 600 cc. of distilled water, to which 3 Gm. of sodium chloride had been added. This mixture was heated almost to the boiling point and after twenty-four hours was filtered through paper. The filtrate was poured into ampules of 20 cc. and was sterilized in the autoclave for ten minutes under a pressure of from 0.75 to 1 atmosphere. The authors emphasize that the solution should be clear. The injections (at first from 16 to 20 cc. and later from 9 to 10 cc.) were given intravenously either daily or every second day in a series consisting of five or six injections. After an interval of several days, a new series was given. The total number of injections varied between fifteen and thirty-eight. In summarizing the results the authors state that in nine cases of pernicious anemia and in two presenting a symptomatology similar to that of pernicious anemia the injections of congo red produced an almost normal blood status. In three other cases of pernicious anemia the combined use of liver and of congo red had favorable effects and the authors emphasize that the quantity of liver alone was not sufficient to produce this result. In three other cases the congo red injections produced no noticeable effect, and liver treatment had to be resorted to.

Blood Protein as Special Organ—Kylin discusses the physicochemical aspects of the blood proteins and emphasizes the difficulties encountered when attempts are made to differentiate between fibrinogen and globulin, on the one hand, and between globulin and albumin, on the other hand. Investigators have pointed out that precipitation and solubility cannot serve as a basis of differentiation, and Bennhold compared the blood protein bodies to the rays of the spectrum, in that the adjoining units gradually blend into one another. Svedberg, however, computed different molecular weights for the different proteins. The authors' own studies seemed to corroborate Bennhold's opinion. He discusses the clinical significance of the blood proteins and stresses particularly their adsorptive or vehicle function. He shows that, if the serum proteins are to be considered a specific organ, it should be possible to find disease conditions that are due to an insufficiency of this organ. He calls attention to the significance of the serum proteins in the water and sodium chloride exchange of the organism. Then he cites factors that seem to indicate a relationship between an increase in globulin and infectious diseases and he believes that the insufficiency of the blood proteins plays an important part in allergic disorders. He concludes that the blood proteins may be considered a special organ but emphasizes that the studies on this organ are only in their beginning stage and that further research is necessary.

Traumatic Leukemia and Priapism—Rösler reports the case of a man, aged 38, whose history disclosed malaria contracted during the war and not entirely overcome until 1925 and gas poisoning contracted in 1931 in the course of working with copper ore. While working as a miner, he was injured by a tool that was driven with force against the root of the penis. He felt nauseated for a short period, but a hematoma did not appear. About thirty-three hours after the accident, the penis and the perineum became extremely painful. Then the penis became stiff and swollen, urination was painful, and the temperature increased. Twenty days after the trauma, the patient complained of severe pains in the left epigastrium and the examination revealed a tumor of the spleen which increased rapidly. The blood showed an enormous increase in the number of leukocytes. The erect penis was sensitive to pressure. The spleen was irradiated with roentgen rays. The priapism showed signs of improvement after the first irradiation of the spleen. After three series of five irradiations each, the leukocytes decreased from 357,000 to 34,800 and the swelling of the penis as well as that of the spleen decreased. When after several months the action of the roentgen rays seemed to decrease arsenic injections were begun and the number of leukocytes became reduced again. The author admits that malaria as well as gas poisoning may cause leukemia but points out that both disorders had existed so long ago that they can hardly be considered etiologic factors, particularly since the patient had been in perfect health for several years previous to the trauma. He thinks that the rapid development of the priapism indicates that in the beginning it was purely traumatic and only later became leukemic, and that there is a connection between the trauma and the leukemia.

*Increased Ray Sensitivity of Skin During Menstruation. L. Freund—p. 182

Rare Forms of Cutaneous Carcinoma—Riecke describes the history of a woman, aged 62, who stated that a year previously a nodule appeared on her thigh. The nodule became enlarged and suppurated and, in spite of treatment, the condition became more severe. After an erysipelas-like process, new nodules appeared and a severe swelling developed in the flexure of the groin, which finally perforated. New nodules appeared repeatedly and always took the same course. They became soft, disintegrated and exuded a serous fluid. In the differentiation of this process the possibility of a syphilitic gumma had to be considered the more so since the physician, under whose care the woman was at first, considered it as such. However, the Wassermann reaction was negative and the process did not have the brownish-red marginal zone peculiar to syphilitic gummas. Blastomycosis and tuberculosis could likewise be excluded. In view of a similar observation, described many years ago by Riehl, cutaneous carcinoma was thought of. Histologic examination revealed a basocellular carcinoma, the origin of which because of its advanced stage, could not be detected. In Riehl's case the cyst formation developed in the fatty tissue and in the muscles. There were smaller and larger cysts with a smooth inner surface and a uniform covering of thin, flat cells. Their development did not correspond to the necrobiosis that produces softening in the parenchyma of a cancer but was traced to the combined influence of the carcinoma and the edema of the lower extremity.

ties. In the case here described, the vascular dilatations and the cyst formations in the noncarcinomatous regions indicated the influence of stasis, whereas the tumour dilatations, within the region of the neoplasm, exemplified a regressive metamorphosis of the carcinomatous parenchyma.

Congenital Pachyonychia (Type Riehl)—Kumer and Loos describe their observations on twenty three cases of congenital pachyonychia. All these patients show thickened finger and toe nails, symmetrical insular keratomas on the plantar surfaces follicular keratoses on other parts of the body, oral leukokeratosis (with the formation of whitish spots on the dorsum of the tongue and on the angles of the mouth) and hoarseness. It was possible to trace the heredity of the pachyonychia through five generations. The transmission was dominant. The ratio of healthy persons and diseased ones was fifty two to twenty-three. Thirteen of the patients were men and ten women. On the basis of their own observations and of those reported in the literature the authors differentiate three types. To the first types belong the cases in which pachyonychia concurs with symmetrical callosities and keratoses of other parts of the skin. To the second type those in which, in addition to the aforementioned symptoms, there is oral leukokeratosis (type Riehl), to the third type those which show, in addition to pachyonychia symmetrical tyomas and keratoses of other parts of the skin and also cornification anomalies of the cornea.

Sensitivity of Skin During Menstruation—Freund observed women who, shortly before and during the menstrual period showed a greater sensitivity to rays than they did ordinarily. He assumes that abnormal circulatory conditions of the skin, the irritability of the vasomotor apparatus and the greater permeability of the vascular walls, which accompany certain conditions in the female genitalia, play a part in this phenomenon. He admits however, that various physical and chemical factors may cause the same disturbance at other times. He considers it possible that many of the cutaneous disturbances, known as menstrual dermatoses, are due to the fact that an endogenic or exogenic factor acts on the vessels, the reactivity of which has become increased. As a result of this increased sensitivity, pathologic changes appear in the skin in response to slight noxae that ordinarily would not lead to clinical manifestations. The author concludes from these observations that it is necessary to exercise especial caution when irradiations are given shortly before and during menstruation. On the other hand, he considers it possible that internal organs which otherwise do not readily react to ray therapy may do so during the menstrual period. He admits, however, that an increased reactivity is not necessarily accompanied by an increased therapeutic effect.

Choreic Syndrome as Manifestation of Cerebral Syphilis—Münzer gives the history of a man aged 45, who contracted syphilis thirteen years ago. Immediately after and repeatedly in the next five years the patient was given anti-syphilitic treatment. About thirteen years after contracting the disease (six weeks before consulting the author) the patient developed motor unrest in the right arm, which had all the characteristics of a choreic hyperkinesia. The unrest becomes manifest as primary, isolated or combined movements that occasionally, by synchronous appearance present the aspect of complicated "motor complexes." Whereas the course of the isolated movements corresponds more to that of Huntington's chorea, the tempo of the motor complexes is more rapid and occasionally resembles a hurling movement. There also exist hypotonia of the same extremity, facial paresis circumscribed

paresthesias in the region of the right thumb and slight increase in the right achilles tendon reflex. Examination of the cerebrospinal fluid revealed the typical aspects of cerebral syphilis. The sudden onset of the hyperkinesia and the fact that it was limited to one extremity makes chorea, due to a focal lesion, seem probable. To be sure, the question of the localization of the focus cannot be answered. In view of the facial paresis and perhaps also of the circumscribed paresthesias of the right thumb the author thinks that a pathologic process in the left optic thalamus or its surroundings is most likely. This would explain also the increase in the achilles tendon reflex. The patient was subjected to fever therapy and subsequently to treatment with neoarsphenamine. These measures effected considerable improvement. The author concludes that this case contradicts those authors who doubt that choreic motor disturbances may be caused by focal syphilitic processes.

Connection Between Radioactivity and Goiter—Lang employed the Elster-Deitel wire activation method in order to determine the amount of products of radioactive disintegration in the atmosphere, particularly in the lower layers, in order to be able to estimate the amount of radioactive gases (radon, thoron and actinon). As the amounts of these gases are influenced by the ground, he made tests in regions with certain geologic-petrographic characteristics. He found again, as he had in previous tests that the atmosphere has the highest values of radioactivity in regions in which goiter is endemic. The values are lower in regions in which goiter is less frequent, and regions that are free from endemic goiter have the lowest values.

Melanoblastoma of Vulva Z Ruffel—p 326

Treatment of Gonorrhea with Living Vaccine—At Schultz's clinic, treatment with living vaccine has been used since 1930. At first he employed living vaccine, obtained from Berlin and prepared on ascites agar from material obtained from new cases of gonorrhea in men. The organisms had undergone two or, at the most, five passages. Thinking that transportation might impair the efficacy of the vaccines, the author later used suspensions prepared shortly before use from the slant agar cultures. Three or four small injections were given subcutaneously into the thigh in fanlike arrangement. In the evening or on the day following the injection, exhaustion was felt by some patients and occasionally subfebrile temperatures developed. After one or three days, an infiltration formed at the site of injection. As a rule, the inflammation disappeared again in from eight to twelve days. In a few cases an abscess formed, which was opened by puncture. The pus contained only gonococci. Focal reactions and changes in the uterine adnexa were not observed. When three days had elapsed after the injection the local and resorbent treatment was resumed again and after ten or fourteen days the injection was repeated. In extremely refractory cases a third and fourth injection may become necessary. The first specimens to test the cure were taken three weeks after the first injection. The author agrees with other observers in considering menstruation a biologic provocation. Consequently he arranges it so that the menstruation precedes the taking of the last specimen. After twelve negative preparations have been secured, the patient is discharged as supposedly cured, but control tests are again made after the three subsequent menstruations. If all these tests prove negative the patient is considered cured. The author obtained more than 70 per cent of cures in 169 cases. The treatment was employed in chronic, not in new, cases. According to other reports, the treatment is of value also in acute cases of gonorrheal arthritis. That the virulence cannot be determined in advance is a disadvantage of the treatment. However, the author emphasizes that in thousands of injections he has never observed a gonorrheal sepsis,

although he admits that other clinics have rejected the treatment with living vaccine

Fecal Concretions Simulating Tumors of Ovary—After citing cases from the literature, in which fecal concretions were mistaken for ovarian tumors, Fischer describes a case. Examination revealed to the right of the uterus two stone-hard, free movable bodies, about the size of walnuts, and one such body to the left of the uterus. Examinations on different days always revealed the same formations. The hardness of the bodies seemed to indicate dermoids. Roentgenoscopy disclosed in the small pelvis four spherical bodies. Enemas and cathartics were without effect. The diagnosis of ovarian tumors was given up when, in the course of an examination under anesthesia, it was discovered that the formations had no connection with the ovaries. Finally, four fecal concretions were removed through the rectum. Sectioning of the concretions revealed circular stratification. The author stresses the importance of a thorough examination under anesthesia in case of suspected disorders of the genitalia.

Perspectives of Surgical Intervention in Clinical Forms of Pulmonary Tuberculosis V L Eynis—p 309

*Abscess of Pouch of Douglas After Appendectomy V S Mayat E M Gindin Finkinshteyn—p 520

Diabetes and Surgical Intervention—Rybushkin and Kalmykov state that the prognosis of surgical interventions in diabetic patients has been definitely improved by the introduction of insulin and proper diet. Such treatment calls for cooperation of the surgeon with the internist. The preoperative treatment is particularly effective in operations for conditions not caused by diabetes. The operative indications for intercurrent disorders may therefore be made much broader than heretofore. Because of serious complications, primary as well as secondary gangrene still constitutes a grave condition. Conservative treatment of gangrene in diabetic patients calls for the greatest awareness of the danger incurred. When amputation is definitely indicated, further delay is not permissible. Local anesthesia is preferable. The influence of blood transfusion on the postoperative alterations in diabetic patients has not been investigated. It has been suggested that the blood of donors fed on a rich carbohydrate diet before the transfusion will lower the blood sugar in a diabetic recipient.

Blood Transfusion—Livshits states that the proper time for blood transfusion in patients having cancer is after the operative removal of the tumor. He advises against transfusion in inoperable cancer, since the transfusion stimulates the growth of the tumor and accelerates its breaking down. The effect of blood transfusion in diffuse peritonitis is negligible. The effect in suppurative processes is favorable and is manifested by the improvement of the general condition and more rapid healing of the lesion. The author warns against blood transfusion in tuberculous patients. His experience suggests that activation of the latent tuberculous process is likely to take place. Among prophylactic measures the advisability of one person determining the groups and reexamining the serums is stressed. Group determination of the donor and recipient must be repeated just before the transfusion, as well as the test for biologic compatibility of the two. The transfusion is to be interrupted at once if the patient evinces even the slightest pain or discomfort.

Abscess of Pouch of Douglas After Appendectomy—Mayat and Gindin-Finkinshteyn report an incidence of abscess in the pouch of Douglas following operation for acute appendicitis in 3.2 per cent of their material (311 cases). They state that the formation of the complication was observed principally in cases in which there were severe pathologic changes in the appendix. Early appendectomy lowers the incidence of this complication. Neither drainage nor primary closure of the abdominal incision without a drain appeared to have a determining effect on the incidence of formation of the abscess in the pouch of Douglas. Among the early symp-

toms the author noted paresis of the external sphincter of the anus and urinary symptoms, such as retention and tenesmus. Rise of temperature and of leukocytosis after an appendectomy are important from a diagnostic point of view. Digital rectal palpation determines the diagnosis of abscess in the pouch of Douglas. Rectal digital palpation must be practiced in all febrile patients after appendectomy. The best method of treatment of the abscess is by incision of the bulging anterior wall of the rectum. In women it may be accomplished by incision of the posterior vaginal wall. The operation is performed under ether or local anesthesia. The late results of the operative treatment are quite satisfactory.

Renal Disorder in Chronic Alcoholism—Vogelius states that Strauss's function test disclosed a disturbance in renal secretion in forty out of fifty cases of confirmed alcoholism. Renal sclerosis was not manifested. Subjective and objective symptoms of nephritis were absent. A slight albumin reaction in the urine, which was often confirmed in these patients and especially in other previously examined alcoholic addicts immediately after hospitalization, practically always disappeared after a day or two in bed but is to be regarded as a sign of slight renal injury due to alcohol intoxication. The renal disturbance took on a grave form in only the minority of the cases and did not on the whole stamp the general picture. A definite tendency to disappearance of the disturbance was seen when the patients lived under favorable conditions. The investigations show, however, that indulgence in alcohol greatly exposes the kidneys to injurious action, contributing to the general breaking down of the organism due to the misuse of alcohol. Examination in thirty-three of the cases revealed gastric achylia in about 50 per cent, polyneuritis, alcoholic amblyopia and dementia were common complications, and dyspepsia and eclampsia somewhat more infrequent, while hematemesis appeared only occasionally, symptoms of cirrhosis of the liver were not established in any case.

Serous Meningitis in Epidemic Parotitis—Johansen reports four certain cases, together with one case of serous meningitis without inflammation of the parotid but with epidemiologic conditions supporting the same etiology. The meningeal symptoms in the four set in at an early stage of the disorder, in three of the cases even preceding the inflammation of the parotid. While the clinical signs of meningitis soon disappeared, constant changes in the spinal fluid persisted after several weeks. Since cases of encephalitis with deeper brain lesions following epidemic parotitis have been reported, rest in bed for several weeks is advocated for patients with parotitis meningitis, in spite of the fact that the subjective symptoms usually disappear in a few days.

Cowpox Infection in Man—In the first of the two typical cases of milkers' dermatosis described by Kristjansen, in persons who had been milking cows with cowpox, the disease was localized only to the point of entry in the hand, in the second, an extensive secondary metastatic exanthem of erythema multiforme type developed.

THE TREATMENT OF PELLAGRA

TOM D SPIES MD
CLEVELAND

It has been known for a long time that pellagra is characterized by remissions and relapses and that the mild cases promptly improve after the assimilation of an adequate diet. Goldberger and his co-workers¹ have produced, prevented and sometimes cured pellagra and have recommended yeast as a specific therapeutic agent.¹⁰ Many diets, drugs and minerals have been advocated by others as certain cures for the disease.² In spite of the application of these recommended methods of treatment all workers agree that the prognosis is very grave for the severely ill pellagrin and that the mortality rate in the advanced stages of the disease is extremely high. It was shown in a previous publication³ that the mortality rate in a series of seventy-three cases of pellagra was 54 per cent despite the fact that all of the patients were given hospital care and offered a highly nutritious diet usually supplemented by yeast. This high death rate is in keeping with that of other hospitals admitting the severely ill.⁴ In contrast to the mortality rate of 54 per cent described in the previous series of seventy-three pellagrins, the mortality rate has been reduced to 6 per cent in a second series of 125 severely ill⁵ by means of the therapeutic measure described in the present communication. The cause of death of each patient in the present series of 125 cases was due, at least in part, to a coexisting disease condition.

It is my purpose in this paper to describe a method of treatment that was found highly successful in the management of the 125 cases of severe pellagra.

5 Each readmission of a severely ill pellagrin was counted in both series as a separate case. The incidence of recurrence in the first series was 10 per cent as compared with 37 per cent in the second group. Were the recurrences not considered as separate cases and only the results of the first hospital admission considered, the percentage of deaths in both studies would have been lower. (It is well known that the prognosis becomes worse with each recurrence of the disease.)

admitted to a clinic for the study of that disease. For four months preceding the formation of this clinic the patients with severe central nervous system involvement persisting vomiting and intractable diarrhea had been treated in the usual recommended manner, but under this treatment the disease progressed and the patient died. By this time methods had been found that were effective in treating the somewhat less severely diseased pellagrin. These methods were then applied to all patients in order to decrease, if possible, the mortality rate of the entire series of severe cases.

The successful treatment of pellagra is governed by the rigid application of certain general and specific therapeutic measures. They are so interwoven in the care of the patient that success depends on the effectiveness of both. In order to make the specific measures more effective, the following general ones must be carried out.

GENERAL PRINCIPLES OF TREATMENT

In the first place, adequate professional and nursing care are essential. All patients with pellagra must have sufficient rest and those who are severely ill must be confined to bed until their improvement warrants additional freedom. Large doses of sedatives are often necessary to accomplish this, but under no condition should they be given in amounts large enough to interfere with the patient's cooperation over long periods of time. Secondly, professional care is essential in order that the pellagrin may receive a well balanced diet containing 4,000 calories or more each day. In the most severely diseased patients the physician must supervise every detail of food intake to make sure that an adequate diet is utilized. It is often necessary for him to cooperate with and instruct the attending nurse and dietitian to see that the food is given in proper amounts at specified times. The physician must see the patient often so that the amount of food lost through vomiting or diarrhea may be evaluated and corresponding additional amounts given. Good nursing care conserves the patient's strength, thus making it possible for him to obtain more rest, which helps promote the effective use of ingested food. Adequate professional and nursing care are also necessary in the local treatment of the lesions, which often makes the patient feel more comfortable and for that reason is desirable, though not necessary in effecting the cure. It need not be said that coexisting diseases must be treated as well as the pellagrous condition itself.

SPECIFIC THERAPEUTIC AGENTS

1 *Yeast*—This material is highly efficacious in the treatment of many cases of pellagra and can be given to mildly and moderately diseased pellagrins. Many of them refuse to take yeast, however, because of its

disagreeable odor and taste, and some learn that it predisposes to vomiting and diarrhea and consequently refuse it. When given in adequate amounts, averaging from 75 to 100 Gm of the dry powder daily, it promotes a desire for food, a feeling of well being, and healing of the lesions. Patients tolerate it best when it is given in doses of from 10 to 20 Gm at intervals of from three to four hours in a glass of either iced milk or iced eggnog until the required daily dose is administered. It is advisable to discontinue yeast therapy when persistent vomiting or intractable diarrhea develops. If the patient already has these symptoms, some other specific curative substance should have preference. On the other hand, if none of the other specific therapeutic agents are available, frequent small doses of yeast should be given, as it is likely that some of the material will be retained until the disease has improved or other therapeutic agents have been obtained.

2 *Desiccated Hog Stomach (Ventriculin)*—This complex substance is composed of defatted, desiccated walls of pig's stomach and has been shown by Sturgis and Isaacs⁶ and Sharp⁷ to be effective in the treatment of pernicious anemia. The indications for its use in the treatment of pellagra are the same as those for the use of yeast and, when given in adequate amounts, elicits a similar response. Desiccated hog stomach has the advantage of being somewhat less distasteful than yeast and does not have the laxative properties. As with the administration of yeast, patients take desiccated hog stomach best when it is given in doses of 20 Gm, well stirred into 200 cc of iced milk or eggnog at intervals of three or four hours until the full dose of 200 Gm or so daily is taken.

3 *Wheat Germ*—This substance is also efficacious in the treatment of pellagra and should be given in amounts ranging from 250 to 300 Gm daily. It is palatable and does not provoke vomiting or diarrhea to the extent that yeast does. In general, the indications for its use are the same as those for desiccated hog stomach.

4 *Liver Extract*—This substance may be given orally or parenterally.

The oral administration of from 75 to 100 Gm of liver extract each day rapidly cures the great majority of patients with pellagra. This preparation is highly palatable and may be given in the same manner as yeast or desiccated hog stomach. It is always a useful supplement to the daily diet of the pellagrins and usually does not cause diarrhea or provoke vomiting.

The parenteral liver extract should be used whenever the patient is dangerously ill. Frequent injections of large amounts of parenteral liver extract are indicated in all patients with persistent vomiting, intractable diarrhea and severe stomatitis. Although these symptoms can often be treated satisfactorily according to the general principles of the care of the patient and by the use of other specific therapeutic agents, the injection of adequate amounts of parenteral liver extract definitely shortens the convalescence and at times proves to be a life saving measure. When liver extract is administered intravenously, it should be given daily in from three to five doses of 20 cc each. This treatment must be continued until the patient shows definite improvement and is able to take sufficient

food supplemented by yeast, desiccated hog stomach, wheat germ or oral liver extract to insure uneventful convalescence.

The specific treatment of pellagra is most successful when one resorts to the parenteral injection of liver extract and the simultaneous administration of large amounts of special antipellagic materials by mouth. In the treatment of pellagra the choice of any one of the therapeutic agents should be based on the advisability of the material, the severity of the disease, and the ability of the patient to cooperate. All agents must be given in large amounts in order to remit the disease quickly and in every instance the general principles for treating pellagra must be rigidly applied.

TREATMENT OF SPECIAL SYMPTOMS

1 *Stomatitis and Glossitis*—More than 50 per cent of the patients with severe pellagra have glossitis and stomatitis. Often the patient refuses to eat because of the painful process of chewing and swallowing food. The physician and patient must realize that the tremendous swelling and reddening of the mucous membranes and tongue will in all instances quickly subside following the assimilation of an adequate amount of a specific therapeutic agent. Mouth washes make the patient feel better and for that reason should be used several times each day. Practically all patients with severe pellagra of the oral cavity have a secondary but extensive infection with Vincent's organisms,⁸ and at times the inexperienced observer fails to recognize the underlying pellagrous condition with the result that antipellagic treatment is not begun immediately and the condition progresses. The teeth should be brushed gently, since severe hemorrhages often occur. Regardless of how severely involved the mucous membranes and tongue become, if the patient can and will take an adequate diet the lesions will usually disappear. The lack of improvement or the progression of the oral changes definitely indicates inadequate or improper treatment.

2 *Diarrhea*—About 60 per cent of the patients with severe pellagra have marked diarrhea⁸ characterized by frequent, large, foul smelling, liquid stools. This condition is exceedingly difficult to treat and yet its persistence is detrimental to the patient. Tincture of opium, 2 cc per dose up to 10 or 12 cc. a day, sometimes assists in checking the number of bowel movements. It should always be given but is particularly indicated whenever a sedative is required. Yeast sometimes increases the diarrhea and for that reason should not be given when other therapeutic agents are available. The administration of a cathartic is naturally avoided under all circumstances. After the pellagrins start definite recovery, the number of stools slowly diminishes and the fecal material becomes more formed and less odorous. Thus it can be clearly seen that, in order to treat the diarrhea, it is necessary to cure the patient of pellagra, for then, and then only, will the diarrhea cease.

3 *Vomiting*—Approximately two thirds of the severe cases of pellagra present persistent vomiting characterized by the retching of mucus and any material that may have been ingested.⁸ Even cold water may provoke vomiting, and at times it occurs despite the fact that no food has been taken by mouth for days. The treatment is absolute bed rest and frequent feedings in from 10 to 15 cc amounts of iced

8 Spies T. D. Unpublished observations.

fluids, such as egg-nogs, malted milk or ginger ale, given very slowly at intervals of from ten to fifteen minutes. These feedings should be supplemented by from 4 to 5 Gm. of desiccated hog stomach, yeast, liver extract or wheat germ until the required daily dosage is given. If the patient refuses these materials or cannot retain them, parenteral liver extract should be given immediately. In all instances, as soon as the vomiting subsides the calorie intake should be increased to 4,500 calories a day by supplementing a well balanced diet with egg-nogs or malted milk, to which one of the specific curative agents has been added in sufficient quantities. If vomiting persists or has persisted for a long time prior to the patient's entering the hospital, subcutaneous injections of physiologic solution of sodium chloride can be given slowly to maintain the state of water and salt balance. The persistent vomiting of pellagra can usually be stopped, but if it continues the patient rapidly becomes worse and the prognosis is more grave.

4 *Abdominal Pain*—An occasional pellagrin enters the hospital with severe abdominal pain, and, as soon as it can be determined definitely that the pain is not caused by a surgical condition, tincture of opium should be given for relief. Abdominal pain in cases of severe pellagra, strangely enough, is usually observed after convalescence begins. This pain is generalized, often severe, and usually somewhat intermittent in character. Since many of the patients soon learn that the ingestion of food definitely increases the abdominal discomfort, they refuse to continue eating, in which case their cooperation can be regained by the generous but not excessive use of opium for a short time.

5 *Nervous System*—More than two thirds of the patients with severe pellagra have manifestations of central nervous system involvement,⁸ peripheral neuritis or a combination of the two. The changes referable to "central neuritis" are characterized by confusion, disorientation, hallucination, dementia and mania. The manifestations often vary from day to day and even from hour to hour, and the patients may recover quickly or after a long period. Contrary to the general experience, the patients in this clinic have nearly always improved (90 per cent), though in some instances months of treatment were required. It is most difficult to achieve proper cooperation in some of these individuals and one may have to use the stomach tube and other methods in order to feed them. Naturally, sedatives are indicated in the manic type but should not be given in doses sufficiently large to render the patient stuporous over long periods of time, for this lessens the ingestion of food and the possibility of escaping infection. These individuals should have a caloric intake of 4,500 calories a day supplemented by ample quantities of a specific therapeutic substance, and they must be protected in order to avoid injury to themselves or others. The patient who once becomes mentally clear for a period of several days is unlikely to become deranged again unless he has a recurrence of the disease.

Peripheral neuritis is one of the most excruciatingly painful of all symptoms associated with pellagra. It usually occurs in the feet and legs, although at times in the hands and arms. It is characterized by hyperesthesia and alterations of the reflexes. While the neuritis is sometimes one of the presenting symptoms of the disease, it usually occurs after convalescence has begun. Large doses of sedatives are necessary for sleep. This condition often leads to a depressed state, and

unless the patients are kept cheerful many of them will obtain large amounts of whiskey or drugs, which may interfere with the desire for food and later prove to be detrimental. Ice bags and local medications containing phenol or menthol serve as temporary expedients and convince the patient that an attempt is being made to relieve his suffering. The signs and symptoms of neuritis may clear quickly or may last for weeks or months, but there is always a complete return of function provided the pellagrins receive adequate calories of a well balanced diet supplemented by one of the specific therapeutic agents. In the severe cases, physical therapy has a therapeutic usefulness.

As yet it has not been determined whether the injections of liver extract cure neuritis. Even though this material may have no direct therapeutic effect on the disturbance in the nervous system, it is conceivable that it might be indirectly beneficial in that it heals the gastro-intestinal tract, which in turn is able to absorb something from the food that might be capable of curing the mental and neurologic symptoms. It must be constantly kept in mind that, even when the patient with severe pellagra receives such a powerful therapeutic agent as large doses of parenteral liver extract, he should also have an adequate diet and rest. His complications and coexisting diseases should be given particular attention as well. It has been found that the small amounts of parenteral liver extract which are so effective in the treatment of pernicious anemia are too small to remit the severe case of pellagra.

6 *Anemia*—More than 60 per cent of the patients with severe pellagra have a definite anemia.⁸ About one third of the patients with anemia have a type characterized by a low color index, while others have an anemia with a high color index and an increased cell volume. The treatment of either one of these types is not an acute emergency and is best begun during the convalescent period. The great majority of individuals improve slowly after receiving an adequate diet. In others, the administration of large amounts of iron hastens the remission of anemia, but the patients with diarrhea must not be given iron until they begin to recover.

7 *Dermatitis*—The characteristic dermatitis of pellagra is of great importance in the diagnosis of the disease. It may occur on any part of the body but is usually found over areas of irritation such as the hands, wrists, elbows, neck, under the breasts, knees, feet, and in the perineal region. These lesions heal easily (often even when the patient receives a diet low in pellagra-preventive material), so they cannot be used as a prognostic index except under one condition, namely, when the patient is receiving treatment and the skin lesions continue to progress for several days, the patient either is not receiving adequate therapy or is not utilizing the given material. The skin lesions of pellagra improve rapidly whenever suitable general therapeutic measures are applied, so that local treatments are never necessary unless secondary infection occurs. Mild antiseptics, however, such as potassium permanganate, 1:5,000 solution used as soaks or on sponges, often give the patient some relief and tend to diminish crust formation and secondary infection. After the skin lesions have begun to heal, the liberal application of ointment of rose water or olive oil prevents pruritus to some degree and increases desquamation.

The treatment of pellagra should not end with the return of health, for the disease relapses easily. The pellagrin must be observed at least once a month in

order to be certain that he is ingesting and assimilating large amounts of a well rounded diet. It requires special attention to afford protection to these patients when they have such predisposing conditions as poverty, chronic alcoholism, acute and chronic infectious diseases, poor teeth, diseases of the gastro-intestinal tract, diabetes, dietary idiosyncrasies, renal disease, surgical operations, insanity, pregnancy and lactation. For example, a quart of milk or 6 ounces of lean meat, when given as supplements to the diet, will usually prevent the development of the disease. Large amounts of turnips, tomatoes and green peas are also effective as aids to the diet.

COMMENT

By the personal application of the principles of treatment outlined, the mortality rate in a series of 125 severely diseased pellagrins was lowered (from 54 per cent in an earlier series) to 6 per cent. The rate of 6 per cent includes every patient with lesions of pellagra, regardless of other disease conditions such as pneumonia, uremia and diabetes, who died during hospitalization even though the pellagrous lesions had healed prior to death.

During the time the mental symptoms of pellagra were being observed, eight patients with delirium tremens but without pellagra were studied also. The patients in each group usually gave a history of heavy imbibition of alcoholic beverages over a long period, followed by the ingestion of smaller and smaller amounts of food. Since delirium tremens and pellagra often follow chronic alcoholic addiction and since the neurologic signs and symptoms of the two conditions are clinically indistinguishable in our series,⁸ it seems possible that the nervous system of the patient with delirium tremens may be involved in a manner somewhat similar to that of the pellagrin who has mental symptoms. Unless delirium tremens is a manifestation of an intracranial pellagrous condition, no patient died from uncomplicated pellagra in our series.

Complete studies including postmortem examinations showed that two of the eight patients dying in this series had extensive bilateral lobar pneumonia, one uremia, one diabetic coma, one delirium tremens and bilateral infarction of the adrenals, one a large pulmonary infarction, one rheumatic heart disease and delirium tremens, and the other manifestations of delirium tremens. It is of general medical interest that three of the eight patients who died had definite cirrhotic changes of the liver.

All patients in these two groups entered either the Cleveland City Hospital or the Lakeside Hospital, and the general type of patient was the same. More than 95 per cent of all individuals in each series imbibed heavily of alcoholic beverages, and pellagra developed secondary to failure of food ingestion,⁹ so the predisposing condition was the same in all instances. The disease represented in each series had the same pathogenesis and predisposing condition and was of similar severity with comparable complications. Were this not so, the present economic situation would have to be considered a factor. It is well known that pellagrins are prone to have recurrences of their disease and, since more of them have been successfully treated in this study, the incidence of recurrence is naturally greater than in the previous series (37 per cent as compared to 10 per cent). It is generally agreed that the prognosis becomes more grave with each recurrence of the disease, so the higher number of recurrences in the present series would tend to increase the mortality rate

in general if all other conditions were equal. It has been shown in the present study that the mortality rate of comparable series of pellagrins was lowered from 54 per cent to 6 per cent by careful personal attention to details of general care, specific therapy, and treatment of complications and coexisting disease. Pellagra could not be considered the sole cause of death in any one of the eight patients who died, as each had extensive involvement of vital organs by other disease processes. In nearly every instance the pathologic changes of fatal disease other than pellagra were ample explanation for death. In four of the cases the pellagrous lesions had healed prior to death.

SUMMARY

It is shown in the present study that the severely diseased pellagrin can usually be cured of his disease, provided he receives sufficient amounts of a potent specific therapeutic agent, adequate rest, food and nursing care. In many instances treatment of the complications and coexisting diseases is essential.

THE SPONTANEOUS HEALING OF
RENAL TUBERCULOSIS

EDWARD L. KEYES, M.D., F.R.C.S. (LONDON)
NEW YORK

From the time that Albarran popularized nephrectomy for the treatment of renal tuberculosis and Wildbolz proved the incontestable superiority of such surgery over the expectant or hygienic treatment of this disease, urologists have vainly sought a pathologic specimen of healed caseating renal tuberculosis with out total destruction of the kidney. To the urologist the tuberculous kidney has behaved like a lymph node. Once it begins to break down it is physiologically lost.

Yet all the while there have been two hitches in the theoretical aspects of the case.

1 The pathologists, aware of the gallant enthusiasm that characterizes surgical theory and practice, have withheld their final judgment. To a pathologist everything is possible. Why not?

2 A few cases have been seen by the urologist, and many have been studied in tuberculosis sanatoriums, of what might be called tuberculous bacilluria. These did not seem to conform to the rule. Such bacilluria may be defined as a condition generally characterized by the appearance in the urine obtained by catheter from one or both ureters of a number—perhaps a considerable number—of acid-fast bacilli, toxic to the guinea-pig. The urine may contain a few red cells and a few pus cells. The patient has no subjective symptoms. The pyelogram shows no deformity. The kidney function is not notably impaired. Most important of all, the lesion may heal, cells and bacilli disappear from the urine and the patient remain well thereafter. Or if the patient dies of concurrent pulmonary tuberculosis or other cause, section reveals no lesion in the "tuberculous" kidney.

In the latter event the pathologist accepts the case as one of healed renal tuberculosis and thinks no more about it. But the urologist comes forward with a choice among several pretty theories.

1 "The healthy kidney can transmit living tubercle bacilli." This is pathologic heresy. A living cell does

not transmit living tubercle bacilli. Moreover, a sufficient number of these cases have shown pus and red cells in the urine to prove there is a lesion—somewhere.

2. Thus the urologist must either grant that renal tuberculosis does heal without total destruction—indeed, without any gross destruction—of the kidney or allege a contamination from tuberculosis elsewhere in the urinary tract, probably in the prostate. This will not hold either certainly not in women.

The cases are so rare that until Medlar made his observations the situation stood thus, urology obstinate pathology patient. In a practice covering thirty-five years and going back to the pre-nephrectomy period I have encountered but one case of tubercle bacilluria and but four patients who having been assured by competent authority (three of them confirmed by guinea-pig) that they had renal tuberculosis (were well and not nephrectomized), when I last saw them.

CASE 1—Acid-fast bacilli in the urine twenty years ago. No symptoms. I removed the patient's hypertrophied prostate last year. He is well.

CASE 2—Schlingensweit made the diagnosis by guinea pig. I saw the young woman a year later with typical elusivc ulcers. There were no bacilli. Renal function was perfect. (A doubtful case.)

CASE 3—A young trained nurse with pain in right loin. Diagnosis by pig (I saw the lesions). Movable kidney. Nephrectomy. No tuberculosis.

CASE 4—Red cells and acid-fast bacilli by smear. Nephrectomy advised but not performed. The patient then consulted me. I have watched him for four years. The urine is normal. Pyelogram negative. Health perfect. Repeated search reveals no acid-fast bacilli.

CASE 5—Man aged 39. Left nephrectomy by me in 1913. The kidney was actively tuberculous. The urine from the right ureter contained no pus, no bacilli by smear. Two guinea pigs were inoculated with urine from the right ureter, one developed tuberculosis, the other did not. Within the next year the patient developed bilateral epididymal tuberculosis and active pulmonary tuberculosis. These were promptly controlled. The patient is alive and well today, in his sixty-first year, twenty-one years after the nephrectomy.

Let me add a note on my one case of exclusively prostatic tuberculosis.

CASE 6—Man. In 1919 bladder symptoms (age 37 years). In 1920 pus and acid-fast bacilli in the urine. The prostate was palpably inflamed. In 1923 cystoscopy was negative, no pus or acid-fast bacilli from either kidney. Bladder urine in two glasses first glass purulent second glass free from pus. In 1924 suprapubic excision of tight bladder neck reported tuberculosis. In 1934 the prostate felt approximately normal. There has been relief of symptoms since operation. No acid-fast bacilli on repeated examinations but still pus in first urine passed. In 1934 he remains well.

Such cases are subject to various interpretations and are not calculated to compose the points of view of laboratory and clinic. Indeed still further confusion is introduced by the periods of quiescence of surgical renal tuberculosis. I have reported two such cases² at intervals respectively of three and six years, one of which showed no cells or bacilli in the urine during the interval. I can now add a third, silent for three or four years.

CASE 7—A woman, aged 21 in 1915. Three months bladder symptoms, pain in right loin, hematuria. Pus and numerous acid-fast bacilli. Typical tuberculous lesion about the right ureter mouth. Urine from the left ureter was normal. Nephrectomy was refused. She became spontaneously well.

She drove a motor transport in New York during the war. Married. Symptoms recurred in 1919. In 1923 urinalysis showed red blood cells. No tubercle bacilli by smear or pig. Cystoscopy by Bugbee negative. Pyelogram showed absence of upper calices, dilatation of lower calices. "Function of left kidney five times that of right."³ Nephrectomy by Bugbee. Typical tuberculosis.

Into this confusion steps Medlar with what should be a clear light. By infinite pains and complete serial section of kidneys from patients showing renal tubercle bacilluria he demonstrates that:

1. Renal tuberculosis is originally a hematogenous lesion, doubtless usually bilateral.

2. There is always a period of initial clinical quiescence (doubtless often lasting several years) during which either:

(a) These lesions heal in one or both kidneys. This is renal bacilluria. Let it be given the term nonsurgical renal tuberculosis.

(b) In one or both kidneys gross destruction of tissue (caseation and so on) occurs. This is surgical renal tuberculosis. The urologist of my generation still regards this as essentially a progressive destructive lesion, requiring nephrectomy to save the patient's life, although most exceptionally (in some 2 to 4 per cent of cases) resulting only in pathologic nephrectomy and not spreading to other organs.

But the pathologists remain unconvinced. Medlar himself seems to encourage clinicians to defer nephrectomy while they tinker with hygiene and quartz lights in the bladder. To me this is dreadful. Even if the nonsurgical kidney may show some minute necrosis and yet ultimately heal, this does not invalidate the surgical position that a tuberculous kidney that shows deformity by pyelogram requires nephrectomy,⁴ not hasty nephrectomy but surely prompt nephrectomy.

Let the urologists who are being seduced to dally with this destructive thus fatal, disease beware. The surgically tuberculous kidney is doomed and even pathologic nephrectomy, rare as it is, often fails to mean healing of the tuberculosis.

CASE 8⁵—Diagnosis of pyonephrosis due to stone in lower ureter. Nephrectomy. The kidney tissue replaced almost wholly by sclerotic fat. The cut surface was smooth and glistening and showed white strands outlining irregular, pink lobules which had yellow fatty centers. A much compressed piece of kidney substance at the upper pole. There was little in the mass to distinguish it as kidney. A number of round tubercles, coagulation necrosis, giant cells.⁵ This therefore is a pathologic nephrectomy, yet the tuberculosis is unhealed.

Contemplate, indeed, what a pathologist means by healed renal tuberculosis. He means that the tuberculosis has healed without destroying the kidney. If the lesion is a surgical one and the kidney has been destroyed by a mixed infection, the pyogenic element destroying the tuberculosis as well as the kidney, that will pass and justly, with the pathologist as healing of renal tuberculosis without total destruction of the kidney by the tuberculosis. But such a finis does not amuse the clinician.

3 Bugbee. Tr. Am. A. G. U. Surgeons 17: 95, 1924.

4 Obviously I do not wish to confuse the text with the problem of treatment of bilateral surgical renal tuberculosis. A patient of mine thanks to ureterostomy lives today with a single tuberculous kidney ten and one-half years after his nephrectomy, but he will die of his disease. The longest survival I have seen was twenty years from nephrectomy though the patient had active bladder symptoms throughout that time sadly impaired renal function and incessant bacilluria.

5 Bugbee. Tr. Am. A. G. U. Surgeons 17: 1924.

1 Keyes E. L. J. Urology 14: 385 (Oct.) 1925.

2 Keyes E. L. Tr. Am. Assn. 7: 17, 1913.

Here is an example. The patient died of pyonephrosis, renal insufficiency and gangrene of the bladder due primarily to renal (and prostatic) tuberculosis. Yet the pyonephrotic kidney shows only scattered, calcified, healed lesions of tuberculosis—the strictures in the ureter nicely proving the character of the calcified renal lesions. The pathologist accepts this as healed tuberculosis without total destruction of the kidney yet, I repeat, the patient died of pyonephrosis.

CASE 9—History—C L, a man, aged 61, admitted Jan 26, 1934, complained of retention of urine and was actually utterly emaciated, dehydrated, semiconscious, moribund. There was a history that fifteen years before he had retention of urine relieved by some form of operation possibly on the bladder neck, possibly an internal urethrotomy. The symptoms were relieved for two years but since that time he had had frequent and difficult urination from time to time and had to be catheterized with increasing frequency until seven weeks before admission complete retention of urine definitely set in and he was treated by intermittent catheterization, under which he daily grew worse until he was brought to the hospital in the condition outlined. Physical examination revealed a blood pressure of 110 systolic, 70 diastolic, a few enlarged cervical nodes moist rales scattered over both lungs but most marked at the right base, a prostate from which pus could be extruded and of which the right lobe was twice the normal size, a bladder distended with urine above the pubes, the urine watery and muddy with pus. The blood urea was 141 mg., blood sugar 150, the Kline test for syphilis was negative.

Carcinoma of the prostate was suspected. Roentgen examination of the pelvis and chest showed no bony metastases but revealed healed tuberculosis of both lungs.

An indwelling catheter was placed and bladder irrigation was done but the urine was so muddy that the catheter could not be kept patent. The next day, therefore, under local anesthesia with the aid of incomplete nitrous oxide anesthesia (in order to control the patient's delirium) a rapid suprapubic cystostomy was done. The finger was swept about the bladder but no tumor of the bladder or prostate was identified. Two shallow diverticula were felt and the persistent thick pus in the urine was noted. A tube was left both in the suprapubic wound and in the urethra. Warm boric acid continuous irrigation of the bladder was kept up through these and in addition to the hypodermoclyses that had previously been instituted a cannula was tied into the median basilic vein and in the course of twenty-four hours 4,000 cc of 10 per cent dextrose solution was given intravenously and this dehydration treatment continued in lesser intensity throughout the illness.

Under this treatment in forty-eight hours the blood urea fell from 141 to 59 mg. A day later it stood at 115 and on the sixth day after operation at 81 mg. Meanwhile the patient had become comatose and developed hiccup, which could not be controlled even by inhalation of carbon dioxide. The urinary output fell from 1,200 to 400 cc a day and on the eleventh day after admission and the tenth day after operation (Feb 7, 1934) the patient died.

Autopsy—The right kidney weighed 180 Gm, with some adherent perirenal fat. It was somewhat larger than usual and the capsule would not strip from it. The entire kidney presented a lobulated vacuolated appearance and felt fluctuant. On section the parenchyma was greatly reduced, the medulla and cortex measuring only 1 cm. at the thickest portion.

The remainder of the kidney was made up of tremendously dilated kidney pelvis and calices containing thick yellow pus. The mucosa of the pelvis and calices was greatly thickened.

Leading from the kidney was a greatly dilated and tortuous ureter with a mucosa similar to that of the kidney pelvis. The ureter had no organic obstruction except the kinking and it entered the bladder through a greatly widened ureteral orifice.

The left kidney weighed 75 Gm. It was much smaller than the right kidney and also felt fluctuant. On section it was composed of merely a thin capsule of fibrous tissue containing very thick pus. This apparently inspissated purulent material was of a whitish yellow, opaque color and was almost pasty in consistency. A part of the lining of the vacuoles composing this

kidney was partially calcified and some of the pasty content had a gritty character. The kidney pelvis, of which the described sacs were extensions, presented a fibrous, rough, thick, mucosa and could not be demonstrated to communicate with the ureter. This ureter was much shorter than the right. It had a lumpy, nodular appearance through its course to the bladder and in many areas its lumen was obliterated. The dilated portions forming the nodules contained a gritty, apparently calcified, whitish yellow, heavy, pasty material. No probe could be passed from the ureter to the bladder.

The bladder was greatly scarred and shrunken. The mucosa was hemorrhagic, edematous and thickened, and it presented two vacuolar offshoots in its fundus, each about 0.5 cm. in diameter, communicating with the bladder by an ostium approximately 0.5 cm. in diameter. The capacity of the bladder was 30 cc. The urethral outlet was unobstructed. The opening of the left ureter could not be found. The right ureteral orifice was as described.

The prostate was slightly enlarged. On cross section there was seen to be in each lateral lobe a nodule composed of several small yellowish nodules, each larger nodule being approximately 1 cm. in diameter.

The seminal vesicles and vasa were not remarkable. The right epididymis contained at the end joining the vas a firm nodule approximately 1.5 cm. in diameter and section of this revealed it to be composed of a brownish yellow purulent material, which was gritty to feel. The left epididymis and both testes were not unusual.

The lungs weighed 735 Gm. At each apex was a fibrous tag where the visceral and parietal pleura were adherent to each other and beneath these were moderate sized depressed scars in the lung tissue. The lungs appeared to contain less pigment than usual and had a billowy blown out appearance, containing many large subpleural blebs. Over the posterior part of the right lower lobe was a depressed red area, and whereas the rest of the lungs felt crepitant this area had a less crepitant, fleshy, feel. Throughout both upper lobes, especially near the apexes, were many hard apparently calcareous nodules the largest of which were approximately 1 cm. in diameter. The tracheobronchial lymph nodes were not unusual, some just below the bifurcation of the trachea were almost completely calcified. One along the right side of the trachea immediately above the right bronchus was partly calcified.

Microscopic examination of the prostate showed two distinct processes. In each lateral lobe there was a circumscribed nodule of glandular tissue in which the acini were lined by a tall columnar one or two layered epithelium containing many papillary infoldings. Into many of these acini there had been marked epithelial degeneration, and many corpora amylacea also were found. The other process was one associated in varying degrees of intensity with lymphocytic, monocytic and plasma cell infiltration of large areas of the organ with an acidophilic necrosis of the more central parts of the areas with a loss of the architecture of the organ here. A similar infiltration was found to surround many of the glandular acini and their ducts. Most striking, however, was the bilateral presence of foci of monocytes and lymphocytes surrounding caseating areas of epithelioid cells and containing giant cells, constituting typical active tubercles.

The middle lobes of the lung showed marked emphysematous changes with widely dilated alveoli, which had in some areas broken into one another, with the broken ends possessing club shaped enlargements.

The lower lobe of the right lung showed a moderate degree of congestion with a filling of alveoli by mononuclear and polymorphonuclear leukocytes in many areas and here and there hemorrhage into the alveoli. The subpleural and interlobular tissues were edematous and the alveolar walls were somewhat thickened.

The right kidney showed a marked diminution of the cortex and medulla with bands of infiltrating lymphocytes scattered through them extending from the pelvis to the medulla. The whole section showed evidence of glomerular and tubular damage. In the worst affected area the glomeruli were only hyaline nodules, and the subadjacent tubules were atrophied or absent. Less advanced changes were found elsewhere, with a

greater or less degree of thickening of Bowman's capsule and diminution in size of the glomerular vessels showing a moderate to advanced degree of hyaline intimal thickening. There was no histologic evidence of tuberculosis.

The bladder mucosa was almost entirely lacking and the small remnants that were to be found were necrotic. The submucosa was edematous and massively infiltrated with wandering cells, most of which were polymorphonuclear leukocytes. In the muscular coat of the bladder there was a moderate degree of lymphocytic and monocytic perivascular infiltration. Just outside the bladder wall were two areas of dense lymphocytic and monocytic accumulation with epithelioid cells in their central portions and some necrosis of the latter. One of these nodules contained a giant cell.

Spermatogenesis was relatively inactive.

The lipid content of the adrenal, as judged by the vacuolization of the cortical cells, was very high, but nothing else of note was to be found.

There was very slight thickening of the larger arterioles of the heart. In several areas near the epicardial surface of the heart were small foci in which the muscle fibers had been interrupted by a process producing fibrous tissue which in some instances was infiltrated with lymphocytes, monocytes and a few polymorphonuclear leukocytes. These resembled small areas of infarction.

The right epididymis was not unusual save for some very deeply basophilic granules resembling calcium deposits in some of the tubules.

The sections of the left kidney were taken through that part of the organ showing the most kidney tissue. There was everywhere replacement of renal tissue by dense fibrous tissue, and the connective tissue thickening in the region of the pelvis was very conspicuous. Scattered diffusely through the connective tissue were small accumulations of lymphocytes. Nothing resembling giant cells or epithelioid cells was to be found. The few renal elements remaining consisted in part of dilated tubules and other more normal appearing tubules which, however, contained an acidophilic coagulation in their lumens. There were a few glomeruli of apparently normal structure but there were many that existed only as fibrous nodules. The intima of all the blood vessels of the sections was greatly thickened.

The mucosa of the left ureter was necrotic and the submucosa was very remarkably thickened by fibrous tissue, most of which was hyalinized. Scattered very sparsely through the latter and through the muscularis were a few lymphocytes, a little more numerous about the adventitial blood vessels.

In the pancreas in some areas there was a very slight increase in connective tissue elements but there were no noteworthy changes.

The spleen weighed 120 Gm. It was remarkably congested and the blood throughout had escaped from the sinuses and had in many areas lost its cellular detail. There was a conspicuous hyperplasia of the mononuclear elements and the malpighian corpuscles were slightly reduced in size and were edematous. The blood vessels possessed moderate to marked arteriolar and arterial intimal thickening.

Culture of the heart blood was sterile. Cultures of the right and left kidneys yielded *B. coli-communis* and enterococci.

The pathologic diagnosis of the significant lesions was gangrene of the bladder, bilateral pyonephrosis, calcareous grit in the right kidney, cardiac infarcts, active prostatic and perivesical tuberculosis, healed tuberculosis of both lungs (superinfection), left kidney, left ureter and right epididymis.

This, I feel, is a good example of a surgical renal tuberculosis for which nephrectomy years ago should have prolonged the patient's life. Yet pathologically it was a healed partial surgical tuberculosis of the kidney.

COMMENT

1 Medlar has shown that renal tuberculosis begins as a nonsurgical lesion that frequently heals.

2 This lesion may be identified clinically as a tuberculous bacilluria (as defined in the text).

3 Surgical renal tuberculosis, characterized by gross changes shown by pyelography, is clinically a progressive disease with a fatal termination unless interrupted by nephrectomy.

4 The pyelogram discloses surgical tuberculosis. The earlier the nephrectomy, the greater the probability of cure.

5 The healing of surgical renal tuberculosis by pathologic nephrectomy is extremely rare and, even with the kidney function gone, active tuberculosis may persist.

6 The pathologist will continue to accept cases like case 9 as evidence of healed partial surgical tuberculosis of the kidney. To the urologist such cases have no interest, for

7 Though surgical renal tuberculosis may remain latent for long periods of time, latency is extremely rare and even in its most complete form, i.e., latency due to complete physiologic destruction of the kidney, the tuberculosis may still actually be active.

8 The curative treatment of renal tuberculosis—old and new—is nephrectomy.

121 East Sixtieth Street

THE STATUS OF THE KIDNEYS IN ALKALOSIS

EDMUND H. BERGER, M.D.

AND

MELVIN W. BINGER, M.D.

ROCHESTER, MINN.

It is an established fact that the kidneys play an important part in maintaining the acid-base equilibrium and thus also in maintaining a constant p_H in the blood and tissues. When this renal function is impaired, the acid-base mechanism is more readily disturbed and the compensating mechanism is more subject to deflection by the ingestion of either acid or basic salts. Conversely, primary renal impairment is very frequently accentuated by overzealous administration of acid or basic salts. We frequently hear of and see instances of depletion of the alkali reserve resulting in compensated or uncompensated acidosis, but rarely do we consider a depletion of the acid reserve with compensated or uncompensated alkalosis and the distressing symptoms associated with this condition. Our present paper concerns itself primarily with the relationships of renal function to alkalosis resulting from the administration of alkalis.

It was early recognized that it was dangerous to administer alkalis to a person whose kidneys had been injured, in amounts sufficient to neutralize gastric acidity. Palmer and Henderson¹ gave 4 Gm. of sodium bicarbonate to individuals and then checked the p_H of the urine at intervals of one and two hours. Normal individuals gave evidence of a maximal rise in p_H in one hour, a few gave evidence of a delayed maximal rise in the p_H of the urine, and the remainder gave no response to administration of the alkali. Members of the latter group had nephritis. Several ingested from 12 to 112 Gm. of sodium bicarbonate before a change of urinary p_H was noted. Sellards² and later Palmer and Van

From the Division of Medicine, the Mayo Clinic.

² Sellards A. W. The Determination of the Equilibrium in the Human Body Between Acids and Bases with Especial Reference to Acidosis and Nephropathies. Bull. Johns Hopkins Hosp. 23: 289-302 1912.

Slyke³ noted that among normal people the ingestion of from 5 to 10 Gm of sodium bicarbonate turned the urine alkaline, at which time the carbon dioxide combining power of the blood plasma was 71 volumes per cent plus or minus 5 per cent. Most of the pathologic urines examined did not become alkaline until a much higher carbon dioxide combining power was present. Palmer and others⁴ noted that when the blood urea was elevated, a larger amount of sodium bicarbonate was required before the urine became alkaline. They explained the variations in amounts of ingested alkali necessary to make the urine alkaline by variations in degree of disturbance of the acid-base regulatory mechanism of the kidney. They found no close relationship between this function and the phenolsulphonphthalein output or the height of blood urea.

Hardt and Rivers⁵ first described, in a very complete manner, the toxic manifestations following alkaline treatment of peptic ulcer, associated with renal changes, increased blood urea, and a normal or increased carbon dioxide combining power of the blood. In three of their sixteen cases of alkalosis definite previous renal injury had been present. They felt that patients with duodenal ulcer and with pathologic changes in the kidneys were more inclined to have toxic manifestations and to a much greater degree, than those who did not have such renal changes. Others since that time have reported cases of alkalosis following ingestion of alkali in which impaired renal function was known to have been present before.⁶ Hardt and Rivers felt that renal injury either inflammatory or vascular in origin increased the tendency to alkalosis on administration of alkali. No definite opinion exists as to the cause for the remaining cases of alkalosis in which the condition is unassociated with pathologic changes in the kidneys. Rafsky, Schwartz and Kruger⁷ and Hardt⁸ felt that many of these patients were sensitive to alkali and that by proper administration, beginning with small doses and gradually increasing the dose alkalosis would not develop. Addis and his co-workers⁹ placed a group of rats on a diet containing 4 per cent sodium bicarbonate for a third of their average lifetime. Of the twenty-four rats in the group, seven had hydronephrosis. All twenty-four presented evidence of microscopic, and many of gross, hematuria, in contrast to groups of rats on an acid diet and a group on a neutral diet the animals composing which had normal urine. At postmortem examination no apparent microscopic difference in the kidneys was seen in the three groups. No other data could be found favoring renal injury by use of alkali. Gatewood and his associates¹⁰ did not recognize nephritis in any

case in which alkalosis developed later, nor did they recognize evidence of renal injury from the use of alkali in any case in their series.

The recognition of this condition is important, not only from the standpoint of immediate care, but also from that of future care. Jordan and Kiefer¹¹ found that 30 per cent of sixty patients unsuccessfully treated medically had had alkalosis. Twenty-three of these patients suffered recurrence of symptoms within one year. They felt that a definite relation existed between hypertension, arteriosclerosis and vascular nephritis since more than one half of the patients in their group were so afflicted.

MATERIAL FOR STUDY

Seven cases were studied in which there were definite symptoms and serologic evidences of alkalosis following intensive use of alkali in the treatment of peptic ulcer.

Although each case will be considered separately later, a few general points first will be made. The patients were all men between 30 and 49 years of age, save one (patient 3), who was 70. This patient had a perforating carcinoma of the stomach. In case 4 an ulcer was not demonstrable either clinically or roentgenologically. The remaining patients had duodenal ulcers. None had a previous history of nephritis. The blood pressure was normal in six of the seven cases. Patients 2 and 3 had palpable peripheral sclerosis graded 1 and 2 respectively. A mild to moderate degree of anemia was present in each case save cases 2 and 7. Five of the patients were admitted to the hospital in a state of alkalosis which had followed the daily ingestion of from 15 to 60 Gm of alkali for from two to four months. In cases 2 and 7, alkalosis developed in the hospital while the patients were on a modified Sippy regimen, receiving about 14 to 16 Gm of alkali daily. The symptoms of distaste for milk, anorexia, nausea and vomiting, weakness, nervousness, mental confusion, dull steady headache, polydipsia and polyuria, numbness and tingling, cramps and, in several instances, tetany were quite outstanding in these cases. The carbon dioxide combining power of the blood ranged from 69 to 84 volumes per cent. We considered any carbon dioxide combining power of 65 volumes per cent or more as being indicative of alkalosis.¹ Impaired renal function was indicated by a value for blood urea of 45 mg or more per hundred cubic centimeters, a return of 45 per cent of phenolsulphonphthalein or less, serum sulphates of 5.5 mg or more per hundred cubic centimeters, and a urea clearance of less than 40 cc of blood cleared per minute (Van Slyke). Other evidence of renal injury was denoted by protein, casts or erythrocytes in the urine.

REPORT OF CASES

CASE 1—A man aged 30, had a ten year history of duodenal ulcer but none of nephritis. Two months prior to his registration at the clinic symptoms of ulcer had become more acute and he had increased his intake of alkali to from 1 to 1½ ounces (30 to 45 Gm) of sodium bicarbonate daily. Ten days later he had symptoms of weakness, dyspnea on exertion, frontal headache, nocturia one or two times, mental confusion, emotional instability and a feeling of uncertainty and vertigo and a profound distaste for milk and a craving for salt.

On examination his face was flushed, he appeared to be depressed and he was confused mentally. The blood pressure in millimeters of mercury was 160 systolic and 100 diastolic.

The heart measured 3 cm to the right and 10 cm to the left of the median line. There was palpable peripheral sclerosis of grade 1. The arterioles of the ocular fundi were constricted, but there was no evidence of sclerosis of the retinal arteries. The specific gravity of the urine was from 1.005 to 1.010 and the urine contained protein graded 2. There was a return of 15 per cent of the phenolsulphonphthalein injected; the value for blood urea was 134 mg, for creatinine 5 mg, and for chlorides 495 mg per hundred cubic centimeters for carbon dioxide combining power 79 volumes per cent and for blood sulphates 10.5 mg per hundred cubic centimeters. The value for hemoglobin and the erythrocyte count were normal. Gastric analysis revealed a free hydrochloric acid value of 18, total acidity of 64, and a content of 150 cc. Fluoroscopic examination of the stomach and duodenum disclosed a duodenal ulcer with obstruction and marked distention of the stomach.

The patient was put on an ulcer regimen. Tribasic calcium phosphate was administered instead of sodium bicarbonate as alkali. Daily intravenous injections of 10 per cent dextrose and 1 per cent sodium chloride solution were given together with from 2 to 3 liters of fluid by mouth. Eleven days after admission the value for the blood urea was down to 48 mg per hundred cubic centimeters, the carbon dioxide combining power to 65 volumes per cent, and the chlorides up to 611 mg per hundred cubic centimeters. The return of phenolsulphonphthalein was 15 per cent, and the protein in the urine remained at grade 1 to 2 with low specific gravity. All toxic symptoms had disappeared. Posterior gastro-enterostomy was performed and convalescence was uneventful. On the patient's dismissal from the hospital fifteen days after operation the value for urea was 44 mg and for creatinine 17 mg per hundred cubic centimeters, the carbon dioxide combining power was 58 volumes per cent, urea clearance was 191 cc of blood cleared per minute, and the urine still contained albumin graded 2, the specific gravity of the urine ranged from 1.010 to 1.016. It is impossible to say how much renal injury was present before the onset of toxicity produced by alkalosis, but it is probable that renal function was impaired to a considerable extent and that this condition was augmented by the administration of large amounts of alkali and, concurrently, that alkalosis was aggravated by impaired renal function.

CASE 2—A man aged 38, gave a history of ulcer of two years' duration, but there was no previous history of renal disease. On admission to the hospital analysis of the gastric content revealed a total acidity of 80 free hydrochloric acid of 72 and a content of 205 cc. Fluoroscopic examination of the stomach and duodenum disclosed a duodenal ulcer. The urine had a specific gravity of 1.023, it contained albumin graded 0 and casts graded 2.

The patient was placed on an ulcer diet with eight alkali powders a day. On the fourth day the value for blood urea was 30 mg per hundred cubic centimeters and the urea clearance 67.6 cc of blood cleared per minute. Five days after the patient's admission polydipsia and polyuria developed and the patient drank from 3 to 5 liters of fluid daily, the urinary output was from 2 to 3.5 liters in twenty-four hours. He also had a bad taste in his mouth, with distaste for milk. On the seventh day milk tasted worse, he complained of pain in the calf of the right leg, and he felt weak, giddy and tired. Chvostek's sign was positive. A test of hepatic function gave negative results. At this time the carbon dioxide combining power of the blood was 79.6 volumes per cent, chlorides were 553 mg per hundred cubic centimeters, and the return of phenolsulphonphthalein was 35 per cent. The urine contained protein graded 2, its specific gravity was 1.011 on a routine specimen and fell to only 1.005 on a dilution test.

Alkaline powders were changed to tribasic calcium phosphate 12 Gm daily and calcium chloride, 4 Gm daily. The fluid intake was raised to 3 liters daily. The symptoms of toxicity from alkalosis disappeared gradually, the distaste for milk being the last symptom to leave, on the seventh day. At the time of the patient's dismissal seven days later the urine still contained albumin graded 1, its specific gravity was 1.011, and the serum sulphates were a little elevated, being 57 mg per hundred cubic centimeters. It is probable that this patient had a latent type of impaired renal function which, under ordinary circumstances, was not of clinical significance.

CASE 3—A man, aged 70, gave a three year history of ulcer symptoms, this condition had become much worse during the three months prior to admission. A roentgenogram of the stomach revealed a large perforated ulcer, high on the lesser curvature, with an accessory pocket, this ulcer was thought to be malignant. Total acidity was 56 and free hydrochloric acid 44. The patient had been taking considerable sodium bicarbonate for relief of pain.

On admission the patient presented symptoms of nausea and vomiting and had a marked distaste for milk. On examination the blood pressure in millimeters of mercury was 120 systolic and 75 diastolic. There was palpable peripheral sclerosis graded 2. The carbon dioxide combining power of the blood plasma was 84 volumes per cent, and the value for blood urea 32 mg and for chlorides 594 mg per hundred cubic centimeters. The value for hemoglobin was 91 Gm per hundred cubic centimeters, erythrocytes numbered 3,800,000 per cubic millimeter of blood and the urine contained protein graded 1 and numerous casts. The specific gravity of the urine ranged from 1.007 to 1.030.

On a carefully controlled ulcer diet together with restriction of alkalis the toxic symptoms cleared up and the pains from ulcer were controlled. Two weeks later the patient was comfortable. On analysis the return of phenolsulphonphthalein was 75 per cent, the value for blood urea 40 mg per hundred cubic centimeters, the urea clearance 71 cc of blood cleared per minute and serum sulphates 51 mg per hundred cubic centimeters. The patient continued on medical management, at his own request despite the possibility of the lesion being malignant. One and a half months later the condition of his kidneys was again evaluated. The value for blood urea at this time was 58 mg per hundred cubic centimeters, the urea clearance was 25 cc of blood cleared per minute, serum sulphates were 62 mg per hundred cubic centimeters, the carbon dioxide combining power of the blood plasma was 58 volumes per cent, blood chlorides were 611 mg per hundred cubic centimeters, and the return of phenolsulphonphthalein was 35 per cent. The patient's symptoms had increased. An exploratory operation was performed and he was found to have an inoperable carcinoma of the stomach graded 4 for which a palliative gastro-enterostomy with entero-anastomosis was done.

This patient undoubtedly had a moderate degree of renal insufficiency probably on a vascular basis, which condition made alkalis less tolerable and resulted in increased renal impairment. The delayed rise in the value for blood urea is of interest and this phenomenon is also frequently observed in cases of acidosis.

CASE 4—A man, aged 35, gave a history of gastric distress of fifteen years duration. He had been treated for duodenal ulcer. Prior to coming to the clinic he had been taking from 1 to 2 ounces (30 to 60 Gm) of alkali powders a day for several weeks. A week before admission he had had nausea, vomiting, anorexia, vertigo and headache. Roentgenograms of the stomach and esophagus at the clinic gave negative results. No acid was found in the first fluid aspirated from the stomach but at one and a quarter hours the total acidity was 38 and the free hydrochloric acid 24. The patient was reported to have spasm of the cardia. The urine contained albumin graded 2 and its specific gravity ranged from 1.005 to 1.010. The value for blood urea was 146 mg, for creatinine 7.2 mg and for chlorides 527 mg per hundred cubic centimeters. The concentration of hemoglobin was 85 per cent and erythrocytes numbered 4,120,000 per cubic millimeter of blood. Unfortunately the value for the carbon dioxide combining power was not estimated on admission. The urea clearance was 139 cc of blood cleared per minute and the sulphate clearance was 10.5 cc of blood cleared per minute. The return of phenolsulphonphthalein was 35 per cent.

The patient was put to bed and took fluids by mouth up to 7 liters a day which he tolerated very well. He passed as much as 7,400 cc of urine in twenty-four hours and the output was consistently more than 3 liters a day. Toxic symptoms cleared up remarkably and in six days the value for urea was 34 mg for creatinine 2.0 mg, and for chlorides 617 mg per hundred cubic centimeters and the carbon dioxide combining power was 47.5 volumes per cent. Before dismissal and after tonsillectomy the value for urea was 18 mg and for sulphates

39 mg per hundred cubic centimeters, and the urea clearance was 455 cc of blood cleared per minute. The urine continued to contain protein and was of low specific gravity, even when normal amounts were passed. Undoubtedly this was a case of renal impairment, aggravated by alkalosis. It is doubtful whether alkalosis would have occurred if renal function had been adequate.

CASE 5—A man, aged 48, presented a history of an intermittent type of ulcer distress for seven years, during the last year the condition had become much more persistent and severe. Eight months prior to admission he had had three gastro-intestinal hemorrhages, these had been associated with fainting and had been followed by tarry stools. He had obtained relief from epigastric pain with milk and alkaline powders and he had resorted to the liberal administration of these, taking from six to eight powders daily.

At the time of admission the patient complained of faintness, headaches, anorexia, and a distaste for milk. The urine had a specific gravity of 1.008 and it contained protein graded 1. The value for hemoglobin was 4.6 Gm per hundred cubic centimeters and erythrocytes numbered 2,860,000 and leukocytes 6,900 per cubic millimeter of blood. The value for blood urea was 78 mg per hundred cubic centimeters, the return of phenol-sulphonphthalein was 30 per cent, the carbon dioxide combining power was 75.8 volumes per cent, and the blood chlorides were 585 mg per hundred cubic centimeters. A test of hepatic function revealed no dye retention.

The patient was given daily intravenous injections of 1,000 cc of a 10 per cent dextrose and 1 per cent saline solution. His fluid intake was kept between 3 and 4 liters a day. Three transfusions were given, and he was put on an ulcer diet, together with restricted alkaline powders to control pain. On gastric analysis the total acidity was 34 and the free hydrochloric acid 0. Two weeks after admission the value for urea had fallen to 26 mg per hundred cubic centimeters. The value for hemoglobin was 8.2 Gm per hundred cubic centimeters and erythrocytes numbered 3,500,000 per cubic millimeter of blood. The carbon dioxide combining power was 60.7 volumes per cent and the blood chlorides were 635 mg per hundred cubic centimeters. The urine contained protein graded 1, and its specific gravity was 1.006. The patient was operated on and a perforating duodenal ulcer was found on the posterior wall. Posterior gastro-enterostomy was done and convalescence was uneventful. Seven days after operation the value for blood urea was 35 mg per hundred cubic centimeters, the urea clearance was 365 cc. of blood cleared per minute, sulphates were 59 mg per hundred cubic centimeters, the carbon dioxide combining power was 47.5 volumes per cent, and the chlorides were 635 mg per hundred cubic centimeters. Protein graded 1 persisted in the urine. The return of phenol-sulphonphthalein was 35 per cent. These postoperative studies of renal function lead one to believe that a mild impairment of the renal function was present and that it was of fundamental importance in the production of alkalosis.

CASE 6—A man, aged 46, gave a history of duodenal ulcer of two years' duration, with hematemesis six weeks prior to his admission to the clinic, since then he had been taking from 8 to 10 teaspoonfuls of alkali powder a day. For about a week prior to admission he had vomited once or twice a day, and he had felt quite dizzy and weak most of the time. Nervousness, irritability, forgetfulness and frequent fronto-occipital headaches had been experienced during this period.

At the time of admission the urine contained protein graded 1, and its specific gravity was 1.013. The value for hemoglobin was 14.7 Gm per hundred cubic centimeters, and erythrocytes numbered 4,060,000 and leukocytes 8,000 per cubic millimeter of blood. The value for urea was 130 mg, for creatinine 2.5 mg, and for chlorides 503 mg per hundred cubic centimeters, the carbon dioxide combining power of the blood plasma was 72.1 volumes per cent. Analysis of the gastric content showed a total acidity of 80 and free hydrochloric acid of 56. The patient's condition did not permit roentgenologic examination of the stomach. Ten per cent dextrose and 1 per cent salt solution was administered intravenously daily, and the fluid intake was maintained at between 3,500 and 4,500 cc daily. Seven days after the patient's admission the value for urea was 26 mg per hundred cubic centimeters, the urea clear-

ance was 48 cc. of blood cleared per minute, blood sulphates were 43 mg per hundred cubic centimeters and the carbon dioxide combining power was 52.8 volumes per cent. The highest specific gravity of the urine was 1.026, the lowest specific gravity in the dilution test 1.004. The urine contained protein graded 1 in three of five tests. The total output of urine in twenty-four hours during this period ranged from 2,000 to 4,300 cc.

An exploratory operation was performed and a subacute bleeding duodenal ulcer was found, for which duodenojejunostomy, reconstruction of the pyloric outlet, and knife excision of the ulcer were done. Convalescence was uneventful. It is difficult to say just how much renal injury was present at the time the value for urea was 130 mg and that for creatinine was 2.5 mg per hundred cubic centimeters. There undoubtedly was renal insufficiency. However, the values were rapidly restored so that in seven days all tests of renal function that were made gave normal values. One must conclude that renal injury in this case was acute but minimal in degree. The patient returned two years later, at which time urinalysis gave negative results and the value for blood urea was 34 mg per hundred cubic centimeters.

CASE 7—A man aged 46, gave a history of intermittent symptoms of duodenal ulcer for two years. On examination, the urine had a specific gravity of 1.028, it was negative for protein or casts. The value for hemoglobin was 17.2 Gm per hundred cubic centimeters, and erythrocytes numbered 4,510,000 and leukocytes 5,100 per cubic millimeter of blood. Roentgenologic examination of the stomach revealed a duodenal ulcer. Analysis of gastric content showed a total acidity of 86 and free hydrochloric acid of 30. The value for blood urea was 20 mg per hundred cubic centimeters.

The patient was given hourly feedings of milk and cream together with 16 Gm of alkaline powders daily. On the fifth day after admission he complained of a dry mouth, of an after taste following ingestion of the powders, that the milk was sour, and of general malaise. On the seventh day he refused his milk because it made him sick. The value for blood urea was 20 mg per hundred cubic centimeters. Urinalysis gave negative results. Cream soup, custard and cereals were given. All symptoms became worse. On the tenth day the patient vomited. At this time the value for urea was 50 mg per hundred cubic centimeters, the urea clearance was 30 cc. of blood cleared per minute, the carbon dioxide combining power was 70 volumes per cent, and blood chlorides were 553 mg and serum sulphates 9.2 mg per hundred cubic centimeters. The powders were discontinued and mucin and tribasic calcium phosphate were given instead. On the fifteenth day the patient was free from symptoms. Studies of renal function at this time showed urea 26 mg per hundred cubic centimeters, urea clearance 60 cc. of blood cleared per minute, blood sulphates 43 mg per hundred cubic centimeters, and a return of phenol-sulphonphthalein of 50 per cent. The dilution test revealed a good output of urine, with 1.001 as the lowest specific gravity. The test of hepatic function showed negative dye retention. Protein, casts and erythrocytes were absent in the urine during the entire period of observation.

It is difficult to explain the alkalosis in this case on the basis of previous renal impairment since before and after the period of alkalosis no impairment of renal function was demonstrated.

COMMENT

Alkalosis is relatively uncommon in the treatment of peptic ulcer. However, the possibility of its occurrence should be kept constantly in mind. The phenomenon usually comes on gradually. The symptoms of distaste for milk, the patient claiming that it is sour, of headache and of weakness are constant, and they occur early. They are noted in the period of compensated alkalosis prior to the characteristic changes in blood chemistry that follow. Later, the other symptoms just referred to appear. Impaired renal function was demonstrated in all the cases during alkalosis. No data were available regarding the previous renal status of the patients. Two of the patients had definitely associated vascular changes.

It is important that the status of the kidneys should be determined in each case before the patient is placed on alkaline powders. If impairment exists, alkaline treatment will probably be unsatisfactory, as has also been pointed out by Jordan and Kiefer. In these cases alkalosis may be rectified by smaller doses of alkalis or by replacement of such alkalis with mucin or tribasic calcium phosphate, with satisfactory control of the symptoms and acids. It must however, be remembered that administration of these substances may also result in toxemia. The mucin, being a protein may in the presence of impaired renal function produce renal insufficiency. In case 7 renal studies gave normal results prior to and following alkalosis, yet with the ingestion of alkalis the carbon dioxide combining power rose to 70 volumes per cent and there was definite renal insufficiency. Neither does the development of alkalosis and renal insufficiency in case 6 seem to be explained by the assumption of a previous renal lesion for, subsequent to toxemia, the patient had normal renal function. The kidney has many functions, and it may be normal in one and deficient in another of these functions. Palmer and Henderson noted delayed excretion of alkali among individuals who apparently had normal renal function.

The question of injury of a normal kidney by prolonged administration of alkalis arises. The work of Addis and the MacKays has been referred to. Stieglitz¹³ is of the opinion that renal injury may result from prolonged administration of alkalis. No definite observations have been made on man in this regard. Recently a patient with duodenal ulcer came under our observation who for years had consumed pounds of both calcium carbonate and sodium bicarbonate every week. No evidence of impaired renal function could be detected.

It is not implied in this paper that alkalosis cannot occur unless there is previous renal injury but rather that, in the presence of renal insufficiency, the threshold of safety is less, and not only that alkalosis is more easily produced in the presence of a preexisting renal injury but also that renal injury is increased concurrently with alkalosis, and thus a vicious cycle is set up. It is to be emphasized that neither basic nor acid salts can be administered with impunity in the presence of renal impairment¹⁴. In the presence of normal renal function, the buffer mechanism maintaining the acid base equilibrium can absorb the assault of either acidifying or basic salts with little or no variation. Furthermore, one should not lose sight of the fact that the liver plays an important part in maintaining the acid base equilibrium and that, in the presence of hepatic insufficiency, this is much more easily disturbed, as is evidenced by the intolerance, in cases of cirrhosis, to ingestion of either acid or basic salts.

SUMMARY

Seven cases of alkalosis were due to administration of alkali in the treatment of peptic ulcer. Evidence of impaired renal function was found in five cases after the alkalosis had been rectified. Previously impaired renal function is an important etiologic factor in alkalosis, and it should be considered in the treatment of peptic ulcer with alkali.

CLINICAL SPECTROSCOPY

SEVENTY CASES OF GENERALIZED ARGYROSIS FOLLOWING ORGANIC AND COLLOIDAL SILVER MEDICATION, INCLUDING A BIOSPECTROMETRIC ANALYSIS OF TEN CASES

L. EDWARD GAUL, MD

AND

A. H. STAUD, BS

NEW YORK

The alarming increase of argyrosis leaves little doubt as to our purpose in this report. There has been an accumulation of indubitable clinical evidence which makes it imperative to present before those who prescribe dispense or use these drugs the danger entailed therein. It must be emphasized that within the past year, following intranasal applications with Argyrol and Neo-Silvol in fifteen children under 10 years of age, an argyrosis developed. Ten of these fifteen children were girls. All these children will present throughout their lives a conspicuous and permanent bluish or slate-gray discoloration that will select them as objects of whispered comments by friends and strangers. At present there is no treatment for argyria.

The obvious responsibility for this injudicious medication rests with the circularized advertisements by the various manufacturers to the physicians, for example, they say:

Argyrol solution, in any strength, may be used in the throat, nose and ear as often as the physician desires, with perfect safety and freedom from irritation. The usual method is to apply a 25 to 50 per cent solution once daily, and to give the patient a 10 to 25 per cent solution for home use in the atomizer in cases where home treatment is desirable.

Internal administration of argyrol, because of the fact that it is non-toxic, is extensively employed in the treatment of gastric ulcer, chronic gastritis, persistent vomiting, typhoid fever and ulcerative enteritis. One capsule, containing five (5) grains of argyrol, followed by a glass of water, should be administered two or three times daily. Neo-Silvol is now quite generally recognized as a valuable therapeutic agent as attested by its growing bibliography and the increasing demand for it.

The injections of Silver-Salvarsan may be given every four days and continued until the desired therapeutic results have been obtained.

The Council on Pharmacy and Chemistry of the American Medical Association omitted argyrol from New and Nonofficial Remedies in 1928, with the following explanation:

The firm presented no satisfactory evidence for the therapeutic claims in question and refused to mention the pharmacopoeial name on the labels and advertising of Argyrol. The Council therefore voted to omit Argyrol from New and Non-official Remedies. W. A. Puckner, Secretary.¹

During the period from 1914 to 1928 thirteen cases of generalized argyria were reported following peroral pharyngeal and intranasal treatment with organic and colloidal silver compounds. Since 1928, however, an additional twenty-seven cases have been reported and observed or an increase of more than 100 per cent within the past five years. Approximately 30 per cent of the cases occurred in persons under 40 years of age and 20 per cent in children under 10 years of age. The sex distribution was about equal. Argyria developed

in 65 per cent following pharyngeal and intranasal applications, and in 35 per cent following peroral administration. The duration of the local and systemic treatment varied from one month to eleven years. Neo-Silvol was used in 20 per cent, Collargol in 22 per cent, and Argyrol in 55 per cent of the cases (table 1).

Silver arspenamine was introduced clinically in March 1918 as another drug in the treatment of

syphilis. Its effectiveness was attributed to the presence of two chemotherapeutic agents—arsenic and silver—and possibly a third role—the catalytic action of silver of the arspenamine molecule. A number of syphilologists have recognized silver arspenamine as a potent drug in the treatment of late cerebrospinal syphilis and advocate its use. Other syphilologists have looked askance at this drug because of the danger of inducing

therapeutic argyria. Five years after the introduction of silver arspenamine Sioli² and Kogoj³ each reported a case of generalized argyria following the use of this drug. The opinions of different observers are not in agreement concerning the maximum dose that can be given without inducing an argyria in the patient. That disagreement undoubtedly explains the development of an argyria in thirteen cases following silver arspenamine during the last two and a half years (table 2). Habermann⁴, Sioli² and Mucha⁵ stated that argyria might occur after 15 Gm of silver arspenamine had been administered but that this condition was not to be feared before this amount had been injected. Myers and Corbitt⁶ were of the opinion that the possibility of argyria from silver arspenamine is extremely remote. Spiegel⁷ stated that many of his patients during the past eight years have received up to 12 Gm of silver arspenamine either alone or in combination with compounds of mercury and bismuth and that no discoloration of the skin has taken place. In the summary and conclusions, he stated that silver arspenamine could not be given to exceed a total dosage of 8 Gm because of the possibility of producing argyria. Becker⁸ believes that the administration of 18 Gm or more of silver arspenamine is apt to be followed by argyria.

A survey of the dosage recorded in table 2 immediately suggests an unrecognized factor. In some patients a discoloration developed after 4, 7 or 8 Gm; in others

It is first necessary to explain the normal occurrence of silver in human tissue. The remarkable achievements in physics, chemistry and metallurgy that introduced the utilization of the mineral elements in the earth's crust have been responsible for the present metal age. These achievements as never before in the history of man offer innumerable sources for the contamination of foodstuffs and water with extraneous metals. Silver has chemical and physical properties that makes it especially suitable in the manufacture of culinary ware, cutlery, casseroles and various appliances to facilitate

Selected biospectrograms illustrating the correlation between the density of the silver line and the degree of skin discoloration.

Case	Degree of Discoloration	Grams Equivalent of Silver Arspenamine
Normal Skin	Normal	0.1 to 0.5 Gm
1 H.E.	Very light	8 Gm
7 W.G.	Moderate	15 Gm
10 H.M.	Very deep	20 Gm

All density measurements were made with a Moll recording microphotometer type A. The method by which these measurements were made have been described in an earlier publication (Gaul, L. E., and Staud, A. H. *Arch. Dermat. & Syph.* 30:433 [Sept.] 1934. *Clinical Spectroscopy: The Advantages and Physical Principles of the Spectrograph and the Technique for Obtaining the Dermal Biopsy Specimen for a Biospectrometric Analysis* (to be published).)

the preparation of foods. While the daily intake of silver from the use of silver or silver-plated appliances is infinitesimal in amount, the total increment from chemical action and mechanical friction over a period of years or decades becomes a sizable amount. Another potential source of silver in human tissue is given in the footnote in table 3.

These remarks have been verified by a series of more than 500 biospectrometric analyses.⁹ An analysis of twenty biopsy specimens obtained from children varying in age from 6 months to 2 years established the normal density of the silver line. In this group of biospectrograms¹⁰ the silver line was faintly visible or visible only with a hand lens. A series of biospectrograms representative of the successive decades of life showed a silver line the density of which was directly proportional to the respective decade from

⁹ The word biospectrometric specifies a quantitative spectrographic analysis for the metallic constituents in differentiated and undifferentiated mesoderm obtained by performing a dermal biopsy with a three sixteenths inch (0.47 cm) punch; the biopsy specimen weighing approximately 0.025 Gm.

¹⁰ The word biospectrogram specifies the spectrogram given by burning a biopsy specimen under standardized physical conditions and obtained with three-sixteenth inch (0.47 cm) dermal punch.

TABLE 3—A Biospectrometric Analysis of Ten Cases of Generalized Argiria Classified According to the Quantity of Silver Present

Cases	Age	Sex	Source of Silver	Degree of Discoloration	Site of Biopsy	Quantity of Silver
1 H.E.	38	♀	Argyrol	Very light	Left knee	8 Gm
2 B.W.	41	♀	Silver arsphenamine	Very light	Shoulder	8 Gm
3 C.F.	43	♀	Argyrol	Very light	Right thigh	8 Gm
4 F.G.	64	♀	Argyrol	Light	Right arm	10 Gm
5 M.L.	51	♂	Argyrol	Moderate	Left knee	10 Gm
6 A.F.	57	♀	Argyrol	Deep	Left knee	15 Gm
7 W.G.	61	♂	Silver arsphenamine	Deep	Right thigh	15 Gm
8 I.K.	43	♂	†	Deep	Forehead	15 Gm
9 E.K.	46	♂	Argyrol	Very deep	Shoulder	18 Gm
10 H.M.	44	♂	Silver arsphenamine	Very deep	Right leg	20 Gm

* The quantity of silver in the biopsy specimens was expressed as grams equivalent of silver arspenamine irrespective of the source, inorganic or organic, from nasal, pharyngeal, peroral or intravenous administration. It was convenient to use this designation since an earlier publication (Gaul, L. E., and Staud, A. H. *Clinical Spectroscopy: A Study of Biopsies from Patients Who Have Received Intravenous Injections of Silver Arspenamine* *Arch. Dermat. & Syph.* 30:433 [Sept.] 1934) established that the quantity of silver in the biopsy specimen was directly proportional to the total dosage of silver arspenamine. † The origin of silver was traced to the electrolytic action between a gold and a silver filling in contact in the mouth. Electrical measurements in additional patients and a subsequent biospectrometric analysis proved that the gold and silver fillings in a medium of saliva form a galvanic cell the action of which causes the silver to go into solution. The rate of solution is determined by such factors as the pH value of the saliva, the surface area of the fillings and electrode potentials.

not until 10, 15 or 20 Gm had been injected. The reason for this obvious lack of uniformity will be explained in the ensuing part of this report.

which the biopsy specimen was obtained. In approximately 5 per cent of the biospectrograms the density of the silver line was an equivalent to that given by a biopsy specimen from a patient who had received from 2 to 5 Gm of silver arsphenamine.

About the most suitable way of explaining the lack of uniformity in dosage in patients in whom argyria has developed following silver arsphenamine therapy is to cite the following example. Let us assume that a white man, aged 50, presents symptoms, signs and laboratory data of late cerebrospinal syphilis. All objective signs of argyria are absent. Normally an individual in the fifth decade of life has a silver retention an equivalent of from 1 to 2 Gm of silver arsphenamine. If during the past any inorganic or organic silver compounds have been used, either as peroral, nasal or pharyngeal medication, the quantity of silver retained will be greatly increased. Supposing the patient had a silver retention equivalent to 5 Gm of silver arsphenamine. The syphilologist, unaware of this, prescribes a routine course of silver arsphenamine. After a total dosage of 7 Gm of silver arsphenamine had been given, an argyria developed. If the syphilologist had been aware of a 5 Gm silver retention by the patient the total dosage could have been calculated accordingly and the argyria prevented.

The example just cited should explain the lack of uniformity of the total dosage in a patient with argyria following the administration of silver arsphenamine. It is possible that the cases in which argyria appeared after 4, 7 and 8 Gm may have shown an existing silver retention before treatment was instituted (table 2). If the syphilologist knows the silver retention, which can now be determined by a biospectrometric analysis, there should be no additional cases of argyria from silver arsphenamine.

A biospectrometric analysis of ten cases presenting objective signs of argyria led to the formulation of the following theorem. The degree of the discoloration is directly dependent on the duration and the intensity of solar or artificial radiation and the quantity of silver present. Argyria becomes clinically apparent after a silver retention approximating an equivalent of 8 Gm of silver arsphenamine, shown in the accompanying illustration. Naturally, whether a person is a blond or a brunette the normal pigmentation will be a further factor modifying the degree of discoloration; another less important modifying factor is the amount of subcutaneous fat. The discoloration in argyria appears first on the exposed areas—face, neck, hands—lunula of the nails—as a result of the chemical action of light on the retained silver.

The pathologic changes in argyria as well as the histochemical studies have demonstrated a uniform distribution of the silver throughout connective tissue.^{10a} Since the corium of the skin is of mesodermic origin or connective tissue, the biopsy specimen will contain the same quantity of silver in the same patient irrespective of the site from which it is obtained, i. e., a biopsy specimen obtained from the area of discoloration and one obtained from the leg or thigh showing no discoloration will contain equal quantities of silver in the same patient (table 3, site of biopsy).

Clinical spectroscopy has not only been successful in establishing the quantity of silver necessary to produce an argyrosis but has been equally successful in demon-

strating the presence of gold,¹¹ lead¹² and nickel¹³ in biopsy specimens.

CONCLUSIONS

1 Seventy cases of argyria have been observed and reported following the indiscriminate use of organic and colloidal silver compounds.

2 The degree of discoloration is directly dependent on the duration and the intensity of solar or artificial radiation and the quantity of silver present.

3 Argyria becomes clinically apparent after a silver retention approximating an equivalent of 8 Gm of silver arsphenamine.

4 A biospectrometric test supplies the syphilologist with a method for determining the silver retention before and during silver arsphenamine therapy.

5 The total silver retention irrespective of the origin should never exceed 7 Gm equivalent of silver arsphenamine.

6 A biospectrometric analysis offers a new diagnostic test for the identification of an argyrosis.

PERIARTERITIS NODOSA

REPORT OF A CASE WITH FATAL PERIRENAL HEMORRHAGE

GEORGE K. WEVER, MD

AND

ISABELLA H. PERRY, MD

SAN FRANCISCO

Periarteritis nodosa is an unusual and relatively uncommon vascular disease. As late as the middle of 1933 only 195 verified cases were to be found in the medical literature.¹ Seventy-seven of these had been reported after 1926. Kussmaul and Maier² in 1866 made the first anatomic description of the disease. In 1878 Meyer³ described a triad of symptoms characteristic of periarteritis nodosa: first, chlorotic marasmus, second, polymyositis and polyneuritis, and, third, gastrointestinal symptoms. Brinkmann⁴ and Christeller⁵ later emphasized nephritis as a fourth cardinal symptom. Arkin⁶ in 1930 described in detail the pathologic lesions. The case reported here presented a clinical picture simulating an acute surgical condition of the kidney so closely that nephrectomy was performed.

REPORT OF CASE

First Entry—T. M., a married man, aged 29, a tilesetter, admitted to the University of California Hospital in the medical teaching service March 30, 1931, complained of intermittent

pain in the lumbar region for seven years, and headache, anorexia and weakness for one year.

The patient had the usual childhood diseases without complication, before the age of 10 years. His second decade was medically uneventful except for gonorrheal urethritis at the age of 14 years and "reinfections" at 17, 18 and 20 years. The patient's father living at the age of 48 had high blood pressure, his paternal grandfather also had had high blood pressure.

Fig 1—Sections of the kidney removed surgically (cleared by Spaltzholz method). The lower section shows an aneurysm ruptured through the cortex as the source of hemorrhage. The upper section shows two aneurysms at the bifurcation of an artery.

In 1923, at the age of 22, the patient had a series of furuncles on the back of the neck, relieved following the use of autogenous vaccine. Approximately one month later there appeared in the course of a few days, a gradually increasing pain across the lumbar region, with swelling of the underlying tissue. The patient was confined to bed for one month, during which time the pain and swelling gradually subsided. He was told at the time, as an incidental finding, that he "had high blood pressure." During the subsequent six years he felt well except for occasional attacks of sore throat and occasional nocturia and diurnal frequency. Tonsillectomy was done in 1929 with relief of the sore throats.

During 1930 there were frequent severe occipital and frontal headaches commencing usually at midday and relieved by a night's rest. Anorexia, vague aching pains in the lumbar region and easy fatigability were noted. Quite suddenly in January 1931 the patient was seized with a severe pain in the lumbar region. Urinalysis at the time showed red blood cells in the sediment. The pain gradually subsided. In the subsequent two months persistent headaches, weakness and loss of weight from 140 pounds to 118 pounds (from 63.5 to 53.5 Kg) led the patient's physician to advise study in a hospital for a suspected renal stone or renal infection.

Physical examination on entry showed that the patient was fairly well developed and in no discomfort. The retinal vessels showed marked sclerosis, the retina of each eye was pale, with scattered white spots around the macula and over the retina. Some of these white patches appeared to be depressed, resembling scars of former hemorrhages. No fresh hemorrhages were seen. The heart was moderately enlarged to the left and the sounds were very forceful. The second sound at the aortic area was accentuated and there was a soft systolic murmur at the mitral area. The rhythm was regular, the rate 110 per minute. The blood pressure was 235 systolic and 150 diastolic. The peripheral vessels showed marked thickening. The prostate was slightly enlarged, more marked on the left with areas of focal induration.

The red blood cell count was 5,200,000 per cubic millimeter, the hemoglobin, 90 per cent (126 Gm) the white blood cells 13,100 and the differential showed polymorphonuclears 74 per

cent, polymorphonuclear eosinophils, 1 per cent, large lymphocytes, 2 per cent, small lymphocytes, 21 per cent, monocytes, 2 per cent. The nonprotein nitrogen of the blood was 33 mg per hundred cubic centimeters. The blood Wassermann reaction was negative. Urinalysis showed albumin varying from a faint trace to a heavy trace. The urinary sediment contained from 1 to 3 white blood cells and 1 or 2 red blood cells per high dry field and an occasional granular cast. The total excretion of phenolsulphonphthalein in two hours was 49 per cent. Cystoscopy showed an old stricture in the posterior urethra and mild generalized hyperemia of the bladder wall. Culture of the bladder urine showed *Staphylococcus albus*. Culture of urine from the renal pelvis was negative. Dye excretion from each kidney at the end of the first fifteen minutes after intravenous injection, was 13 per cent. Roentgen study of the left kidney, after injection of sodium iodide through the ureteral catheter, showed the organ to be normal in appearance except in the upper calix, where some changes were noted but which were thought to be due to overdistention.

During the patient's eighteen-day stay in the hospital there was an irregular daily elevation of the temperature to a maximum of 37.8 C (100 F). The pulse rate was rapid. The blood pressure remained elevated. Symptomatically the patient improved. On discharge he was advised to continue moderated activity, a low protein low-salt diet, prostatic massage and bladder irrigations. The diagnosis on discharge was marked arteriosclerosis and hypertension, chronic nephritis of the arteriosclerotic type, chronic prostatitis and cystitis.

Shortly after discharge the pain in the lumbar region recurred and persisted with moderate severity throughout the next three months. Weakness and headache were progressive and the patient also noted rapidly failing vision. Distention of the abdomen, nausea, vomiting and constipation became prominent. The blood pressure remained elevated to about 210 systolic and 140 diastolic.

August 22, the evening before the second entry, the patient was sitting quietly in a chair when he was suddenly seized with a severe pain in the right lumbar region. The pain was intense and sharply localized for several hours, and the overlying muscles seemed to be "tied into a knot." The position of flexion was most comfortable. Chiropractic manipulations were administered and relieved the muscle spasm slightly, but there was considerable soreness in the lumbar region and a pain was noted in the lower right quadrant of the abdomen. A physician

Fig 2—Longitudinal section through the left kidney showing aneurysms and mal dilatation of the arteries.

was called who administered opiates and advised immediate removal to the hospital.

Second Entry—On this entry, August 23, the patient was restless, irritable and markedly undernourished. He appeared to be acutely ill and complained of acute pain in the right lumbar region. The skin and mucous membranes were pale. Both ocular fundi showed hazy disk margins. The disks and surrounding retinas were paler than normal and the small tortuous arteries appeared almost bloodless. Patches of white exudate surrounded the vessels, and about the maculae there

were star-shaped patches of exudate. The carotid pulsations were forceful. The heart was enlarged to the left. The first heart sound was split in a sharply localized area at the apex. The second sound was markedly accentuated especially at the aortic area. No murmurs were heard. The rhythm was regular. All the palpable peripheral vessels were markedly thickened. The blood pressure was 185 systolic and 125 diastolic. On palpation the abdominal wall was rigid and tender. An irregular mass was identified in the right upper quadrant,

Fig 3—Right internal mammary artery and vein. The large nodules were embedded in the intercostal space. Communication of these nodules with the arteries could not be demonstrated. The smaller nodules were in communication with the arteries. They had thick fibrous walls with a minute central blood clot. Occurrence of the nodules at the bases of the branching arteries may be noted.

apparently extending through the depth of the abdomen. The right lumbar region was exquisitely tender both to superficial and to deep palpation. The spine was held immobile by the rigidity of the paravertebral muscles on the right.

The red blood cell count was 1,800,000 per cubic millimeter, hemoglobin 30 per cent (42 Gm.), white blood count 15,400 per cubic millimeter with a differential of polymorphonuclears 79 per cent, polymorphonuclear eosinophils 1 per cent, lymphocytes 18 per cent and monocytes 2 per cent. The smear showed achromia. The nonprotein nitrogen of the blood was 46 mg. per hundred cubic centimeters. Repeated urinalyses showed albumin in amounts varying from a moderate to a heavy trace. The urinary sediment contained hyaline and granular casts and frequent white blood cells but no red blood cells. The total excretion of phenolsulphonphthalein in two hours was 30 per cent. Repeated examination of the stools for occult blood was negative. Cystoscopy showed diffuse injection of

the bladder wall with a trigonitis. Roentgen study of the right kidney, after injection of sodium iodide through a ureteral catheter, showed the renal pelvis to be normal except that it was displaced outward. It changed position very little when the patient was in the vertical position. There was a suggestion of a rounded soft tissue shadow down the right side of the spine. Study of the colon with a barium enema was negative. On roentgen study the chest heart and lungs appeared normal.

There was gradual slight improvement in the patient's condition during the first thirteen days of residence. A persistent irregular fever with the maximum to 38 C (100.4 F), a continuously rapid pulse rate, persistent leukocytosis, the presence of the abdominal mass and the pain in the lumbar region led to a diagnosis of perirenal abscess and were considered indications for operation.

The patient was transferred to the genito-urinary service of Dr. Frank Hinman. A right nephrectomy incision was made and a large firm mass bulged into the wound. The tense perirenal fat was broken through with the expulsion of a large amount of clotted blood. The hematoma was found to be in and beneath the perirenal fat and infiltrated about the kidney. A right nephrectomy and adrenalectomy were performed. The source of the hemorrhage was not found. There was no untoward bleeding during the operation and the renal fossa was dry when the wound was closed.

Following the operation a transfusion of 525 cc. of whole blood was given from a compatible donor. For several hours

thereafter the patient appeared to be in good condition. Eight hours after the operation he complained of severe abdominal pain and presently went into shock. Two hours later he died of respiratory failure in spite of supportive measures.

PATHOLOGIC STUDY

The specimen consisting of the kidney surrounded by a mass of blood clot weighed 450 Gm. The kidney, when dissected away from the clot weighed 130 Gm. There were fragments of the adrenal gland in the blood clot. On cut section numerous dilated thrombotic vessels were noted in the renal cortex. One of these had ruptured through the capsule and was probably the source of the perirenal hemorrhage (fig. 1). The renal tissue was coarsely granular and the arteries were thick walled. The histologic changes corresponded to those to be described in the postmortem tissues.

The necropsy was performed eleven hours after death. There was a slight baldness on the crown of the head. The left axillary lymph nodes were palpable. There was a recent unhealed incision in the right lumbar region, closed by sutures.

When the abdomen was opened, the cecum was seen to be pigmented with fine black particles, which proved to be recent subserosal hemorrhages. There were several encapsulated masses of dry blood in the mesentery. The viscera otherwise appeared to be normal in size and position.

When the thorax was opened three nodules about 8 mm. in diameter were noted along the course of the internal mammary artery (fig. 3). These all contained old dry blood. The pleura and pericardium were normal.

The heart weighed 400 Gm. Two gray, firm, translucent nodules 0.5 cm. in diameter were observed on the anterior surface of the right ventricle. These nodules lay in contact with an artery. On section they were seen to be completely organized and had no lumens. There were no valve defects. The coronary arteries were not sclerosed. There was extreme left ventricular hypertrophy without dilatation. The left ventricular wall was 30 mm. thick, the right was 4 mm.

The lungs were relatively normal. The dependent parts were moderately congested. No nodules were noted.

The liver weighed 1,800 Gm. It was pale yellow except for several depressed red areas on the surface. These areas were irregular in outline. The largest one was 4 cm. in diameter. On section the lobular architecture was distinct except in areas of intense congestion such as those noted on the surface. These areas usually had a very thick walled artery in their center. There were also numerous encapsulated masses of old dry blood similar to those occurring in other organs. These were aneurysms and usually occurred at the side of a thick walled artery. Communication with the lumen of the artery was not observed. The hepatic artery was small and cordlike without a visible lumen.

The spleen weighed 185 Gm. It was pale pink and rather soft. One large and several small aneurysms were present in the parenchyma. The large one was 2 cm. in diameter.

The splenic artery was opened along its course. There was a very marked atherosclerosis. The plaques were soft and were conspicuous in size and thickness at the mouths of the arterial branches so that the orifices of the branches were very small. Encapsulated masses of dry blood occurred in nodules along the course of the splenic artery. These nodules did not appear to have arisen within the pancreas but encroached on it.

The stomach was dilated, containing about 120 cc. of watery fluid. There were a few congested vessels in the submucosa. Two encapsulated masses of hemorrhage were found beneath the mucosa. The largest one was about 2 cm. in diameter. Its periphery was bright yellow while the center was dark red. Along the course of the right gastroepiploic artery and the left gastric artery were many small nodules. Some contained dried blood and some were completely fibrosed. The

Fig 4—Cross section of pancreas showing an aneurysmal dilatation of the splenic artery compressing the pancreas.

nodules were nearly always at or near the root of a branching vessel. A few nodules were found in the mesentery. There were no other lesions in the alimentary tract. The posterior peritoneum was pushed forward by the perirenal hemorrhage. This mass of hemorrhage extended from the diaphragm to the brim of the pelvis. It filled the whole right flank and extended a little over to the left side.

The ligatures at the hilus of the amputated kidney were examined in situ and found securely tied. The middle right

Fig 5—Artery showing the intimal proliferation and infiltration with eosinophils

adrenal artery projected as a stump into the mass of hemorrhage. There was a nodule just proximal to the severed end of the artery. This adrenal stump was the apparent source of the last hemorrhage. Fragments of the adrenal gland were found in the mass of hemorrhage. As far as could be determined the gland was normal except for fragmentation. Three nodules containing old blood occurred along the course of the middle adrenal artery on the left side.

The left kidney was pale. The surface was finely granular. It appeared to be within normal limits in size. The structures at the hilus were normal in their relations. The renal artery was moderately sclerosed. On section, a number of nodules were found throughout the kidney (fig 2). These were never more than 8 mm in diameter. In some the dry blood was red and in others brown. The bladder and prostate appeared to be normal. There was a small unencapsulated area of brown pigmentation, apparently old blood, in one testis.

The aorta and the iliac arteries showed moderate sclerosis with atheromatous plaques along the intima.

The arteries at the base of the brain showed a well marked atherosclerosis. When an attempt was made to tie one of the internal carotids, the vessel broke repeatedly under the suture. No hemorrhages or nodules were found in the brain. The skeletal muscles and eyes were not examined.

For brevity the microscopic appearance of the lesions in organs other than the kidneys will be described only as they showed some change not present in the kidneys.

Both kidneys showed a slight diffuse fibrosis. The glomeruli were little changed. Occasionally there was some fibrin and serum in the capsular space. The capsules were slightly to moderately thickened. The tubular epithelium was degenerated in some fields, and in a few areas the tubules were dilated by hyaline casts. Small recent infarcts were noted. There was a conspicuous intimal thickening of the arterioles with a corresponding reduction in the size of the lumen (figs 5 and 6). Several aneurysmal nodes occurred. They had walls comparable to those of medium sized arteries. In some instances the thin hyalinized wall was concentrically dissected apart by recent hemorrhage (fig 7). In the walls of these nodes one rarely found a stippling of calcium (fig 8). A lymphocytic

infiltration of the wall was common. Rarely a few polymorphonuclear leukocytes were found in and about the walls dissected by hemorrhage. Hemosiderin-laden macrophages were present. The lumens of some of the nodes showed early stages of organization. At the periphery of the older nodes the blood pigment was collected and stained a bright orange (hematoxylin-eosin stain). The right perirenal hemorrhage showed early organization.

In the heart and along the splenic artery, some of the lesions appeared to be more recent. In the nodes along the coronary arteries hyaline necrosis of the muscularis occurred. Repair of the vessel wall was evidenced by fibroglial proliferation. Eosinophils were scattered throughout the wall and around the nodules on the splenic artery. The lesions of the splenic and coronary arteries appeared to be more recent than those of the kidney.

The anatomic diagnosis was 1. Periarteritis nodosa involving the mesenteric, hepatic, splenic, renal, adrenal, gastric, cardiac and internal mammary arteries. Recent right nephrectomy, extensive right perirenal hemorrhage. 2. Arteriosclerosis most extensive in the pancreatic, splenic and cerebral arteries.

COMMENT

The duration of the clinical symptoms of this disease is said to be from a few weeks to six months, rarely a year. However in one of the instances reported by Arkin⁶ the patient lived four years after his one and only attack of acute illness. When he eventually died, from cardiac and renal insufficiency, histologic evidence of old healed lesions of periarteritis nodosa were found at autopsy. Seven years before his death our patient had an acute illness which might be interpreted as an acute exacerbation of this disease. The finding of a hypertension at the time of this first illness is presumptive evidence at least of the presence of the disease at that time. There was then a long period of freedom from symptoms, during which time it may be assumed

Fig 6—Artery showing intimal proliferation

that the lesions underwent healing and the disease became quiescent.

Our patient was referred to the hospital by his private physician because of a suspected renal stone. After the first period of observation a diagnosis of chronic nephritis was made. Six months later a diagnosis of perirenal abscess seemed justified and an operation was performed. A perirenal hematoma was found and the kidney with the surrounding hematoma was

removed. The patient died ten hours after the operation from another massive hemorrhage into the renal fossa. On studying the histories of other patients with periarteritis nodosa it is found that all these diagnoses have been made, erroneously, from time to time.

The frequent involvement of the kidney in this disease has been emphasized by Gruber,⁷ who found an incidence of 74 per cent involvement, and by Arkin,⁶

Fig 7—Wall of an artery showing hemorrhage and organization

who found an incidence of 80 per cent involvement. The usual clinical signs pointing to the kidney are those of a nephritis and consequently the most frequent clinical diagnosis has been "hemorrhagic nephritis." Acute surgical conditions of the kidney have been diagnosed occasionally. In two of the cases reported by Hauser,⁸ operations were performed because of a mistaken diagnosis of an acute surgical condition of the kidney. Gray⁹ reported a case in which a preoperative diagnosis of perinephric abscess was made. The patient died five days after operation and the lesions of periarteritis nodosa were found at autopsy. Keegan¹⁰ reported a case in which a "surgical condition of the kidney" was suspected, and the operative specimen showed the changes of periarteritis nodosa. Wordley¹¹ reported a case in which a diagnosis of renal calculus was made and then later changed to renal neoplasm. When the patient died about two months after the onset of the illness, autopsy again showed the lesions of periarteritis nodosa. In at least eight cases of periarteritis nodosa found in the literature,¹² death has been due to renal or perirenal hemorrhage.

Goldstein and Wexler¹³ have described the pathologic changes in the retinas of a patient dying with periarteritis nodosa. Although the fundi of their patient were reported as being normal during life, the authors suggested the possibility of ophthalmoscopy being of aid in recognizing the periarteritis nodules on the choroidal vessels of other patients. Gruber¹⁴ tabulates thirteen cases with ophthalmoscopic examinations. All these patients had renal lesions. In eight of them the fundi were reported as normal and in three an albuminuric retinitis was described, so he concluded that the changes were secondary to the renal lesions. Friedenwald and Rones¹⁵ have made pathologic studies of the retinas in periarteritis nodosa and found that the vessels showed an extreme degree of arteriosclerosis and did not differ in any way from those found in an ordinary uncomplicated albuminuric retinitis. The ophthalmoscopic picture thus far described in patients with periarteritis nodosa does not seem to be characteristic of the disease, but it is possible that in some cases correct diagnosis may be attained by the finding of tubercle-like lesions on the choroidal vessels. On the other hand, this finding might serve to confuse the diagnosis by bringing up the possibility of tuberculosis. In our case the retinal changes were described by the consulting ophthalmologist as being those of albuminuric retinitis. The long standing hypertension, with its resulting sclerotic changes, and the nephritis would readily explain the picture. Unfortunately, a pathologic study of the retinas was not made.

Herrman¹⁶ has noted changes in the roentgenograms of the chest of a patient with periarteritis nodosa. He felt that these changes were probably due to vascular and perivascular inflammation and exudation together with associated congestion and small infarcts. He was

Fig 8—Wall of an artery showing deposits of calcium and fatty acid

of the opinion that confirmation of these changes in other patients with the disease is necessary before they can be considered characteristic of the disease. Roent-

genographic studies of the chest of our patient showed the lung fields to be clear.

The general symptoms of this disease are those of any acute or chronic sepsis. The local manifestations are extremely variable because they are governed by the site of localization of the vascular lesions. Correct diagnosis during life is therefore very difficult. According to Rothstein and Welt,¹ only seventeen cases out of 195 (8.7 per cent) have been diagnosed accurately during life from the microscopic examination of a subcutaneous nodule removed by biopsy (twelve cases) or of a specimen removed at operation (five cases). In seven other cases a tentative diagnosis based on clinical symptoms alone was made and subsequently proved by autopsy.

At the present time it appears that the hope for more accurate diagnosis of periarteritis nodosa during life lies in the recognition of the existence of such a disease by the clinician and the inclusion of it in the differential diagnosis of unusual medical and surgical problems. Rothstein and Welt¹ aptly stated that "periarteritis nodosa should be considered in every case of acute or chronic sepsis with sterile blood cultures and a bizarre symptomatology unexplainable on a common basis particularly if associated with a severe anemia, a febrile course, gastro-intestinal symptoms, manifestations in joint, muscle or skin and signs of renal involvement together with an elevated blood pressure."

The etiology of periarteritis nodosa is obscure. Various theories have been advanced, the most acceptable of which proposes that the disease is infectious in origin. The very nature of the pathologic lesions suggests an infectious etiology. At the present time neither a filtrable virus nor a nonfiltrable micro-organism has been demonstrated as the causative agent. Culture of a smear taken from a mesenteric nodule at the time of autopsy of our patient showed *Staphylococcus albus*. As the autopsy was performed eleven hours after death, there was probably adequate time for organisms from the gastro-intestinal tract to invade the surrounding tissue.

The pathologic studies suggest that the causative agent has a predilection for arteries. It produces a patchy destruction of the media. The lesions tend to heal but complete morphologic and functional recovery does not take place. An aneurysm may develop in the weakened wall, or the lumen may be reduced or obliterated by the scar. The aneurysms, when they occur, may be completely walled off from the circulation and may show organization throughout. The lesions are not all in the same stage of the disease at the same time.

In this case the aneurysms were frequently found at the bases of the small arteries immediately distal to the point of branching from larger vessels. A tentative mechanical explanation of this finding is suggested by the fact that the intravascular pressure in the branching artery is highest at its base and diminishes progressively toward the periphery. The wall of the damaged vessel would be most likely to give way and form an aneurysmal dilatation in the region of greatest internal pressure. Forbus¹⁷ has noted the occurrence of miliary aneurysms of the cerebral arteries at the angle formed by a branching vessel and has demonstrated a defect in the muscularis layer of the arterial wall, in normal and pathologic cases, at the point of bifurcation of the vessel.

Nieberle¹⁸ has called attention to a disease found in deer, cattle, swine and dogs very similar or identical to periarteritis nodosa in man. Experimental studies with these animals might aid in clarifying the etiology and natural course of the disease.

SUMMARY

1 A diagnosis of perirenal abscess was made on a patient with a mass in the upper right quadrant of the abdomen, pain in the lumbar region, fever and leukocytosis. An operation was performed and a perirenal hematoma was found. The patient died a few hours after operation from a second hemorrhage into the renal fossa.

2 Necropsy revealed the characteristic lesions of periarteritis nodosa involving the mesenteric, hepatic, splenic, renal, adrenal, gastric, cardiac and internal mammary arteries.

3 The history suggests that the duration of the disease in this patient was seven years.

4 The pathologic study showed that the aneurysmal dilatations were most frequently found at the base of a branching vessel.

The University Medical Center

A CASE OF SPONTANEOUS HEMOPNEUMOTHORAX

JOSEPH L. FREY, MD

NEW YORK

Hemopneumothorax is not a common condition. The majority of cases follow trauma, either in military or in civil life, but the spontaneous form is distinctly rare. After a scrutiny of the literature for the last thirty-four years I have been able to find only thirteen recorded cases.

Ten of these reported cases deserve to be called spontaneous for lack of any definite cause, such as demonstrable disease or trauma. The remaining three were due to tuberculosis and one of them was complicated by artificial pneumothorax. Among the ten spontaneous cases three were fatal and seven patients recovered, of the three tuberculous patients, two recovered and the one with artificial pneumothorax died. These thirteen cases are all true cases of hemopneumothorax and not just hemothorax or pneumothorax. The term hemopneumothorax should be applied to cases of lung collapse with undoubted blood and air within the pleural cavity and not just blood-stained serum (hemorrhagic effusion), such as is occasionally seen in malignant disease of the lung.

THIRTEEN CASES FROM THE LITERATURE

CASE 1—Dr G. Newton Pitt,¹ who recorded a case in 1900, states that "there is no reference to hemopneumothorax in the Index Catalogue of the United States Library, nor is it discussed in any of the standard treatises on medicine in English, French or German" and at that time he could find only one case in the literature unassociated with trauma. This case was recorded in the Guy's Hospital records and revealed a case of hemopneumothorax due to the rupture of an aneurysm in a large phthisical cavity at autopsy. Pitt's patient was a young man who was seized with sudden pain in the right shoulder and who collapsed. There were signs of fluid and air in the right side of the chest. A Southey's tube was inserted into the sixth space in the right axilla, with the removal of blood and

¹ Pitt G. N. *Tr. Clin. Soc. London* 33: 90, 1899, 1900.

air. Death ensued the same day. Autopsy revealed no tuberculosis and the only abnormality was a pleural adhesion and an emphysematous bulla, which had ruptured. The adhesion from the bulla to the pleura was torn across. No obviously patent vessel could be seen, but the adhesion was suggested as a probable source of the bleeding.

CASE 2—Sir Humphry D. Rolleston,² also in 1900 reported another case. A young man was seized with pain in the right shoulder and right hypochondrium. The abdomen was resistant and did not move well, the liver dullness was normal. Twenty-five hours after the acute onset he was in extreme collapse and with a pulse of 160, running in character and irregular. Three days later the signs were those of a pneumothorax. On the following day the trocar of an aspirator was inserted into the sixth interspace in the right anterior axillary line, a tube attached to the trocar was brought up under water. Although the chest was hyperresonant, only dark blood came out. As it appeared possible that the trocar had passed into the liver and drawn off blood from a large branch of the portal vein, it was withdrawn and again introduced in the fifth right interspace in the parasternal line. Air then came bubbling out at high pressure from the tube under water, as the air escaped it was followed by dark blood, which also came out at considerable pressure. The patient died eight days from the onset. At autopsy the right pleural cavity contained 60 ounces (1,775 cc) of dark fluid blood with a few ounces of blood clot. There was no evidence of lung rupture, no tuberculosis, no leakage from the pulmonary artery, there were normal glands of the chest, normal intercostal and internal mammary arteries and no signs of scurvy in the joints with no evidence of the source of blood or air into the pleural cavity.

CASE 3—Ness and Allan³ in 1910 reported that a clerk, aged 31, was seized with pain and tightness in the left side of the chest, and dyspnea. There were marked signs of hydro-pneumothorax. A thoracentesis was done and 5 ounces (148 cc) of blood mixed with serum was removed. No further thoracentesis was done. Six weeks after admission all signs had disappeared and the patient went back to work. Three months later he was perfectly well. Examination of the sputum always gave negative results.

CASE 4—Thomas Bushby⁴ in 1913 reported the case of a youth, aged 17 with a spontaneous hemopneumothorax with collapse. The chest was tapped twice and bloody fluid removed each time following which signs of pneumothorax persisted for a while and finally ended in recovery and discharge. There was some suspicion of the patient being of a hemorrhagic diathesis, which was supported by the fact that troublesome bleeding had occurred on the occasion of the extraction of teeth and that he had bled freely from small wounds. The case was regarded as one of rupture of the lung, probably due to a small superficial cavity with simultaneous laceration of a small vessel.

CASE 5—Charles Spencer Williamson⁵ in 1917 reported that a young man, while drinking water over a faucet, felt something 'crack' in the left side of the chest with pain and signs of collapse, coming on gradually. The signs of hydro-pneumothorax with succussion splash and coin sound were elicited. During several months the chest was aspirated twelve times with from 12 ounces (355 cc) to 1 liter of bloody fluid being removed each time. Cultures of the fluid remained sterile. Inoculation of the fluid into a guinea pig did not lead to the development of tuberculosis in the animal. Tumor was ruled out. No sputum was obtainable. The patient's recovery was uneventful. In spite of all the negative tests Williamson expressed the belief that the pneumothorax was caused by either a small emphysematous bleb or a small focus of tuberculosis. The hemorrhage he explained as old adhesions in the vicinity of the apex with perhaps development of ectatic veins or a solitary aneurysm.

CASE 6—Krause and Heise⁶ in 1920 reported an unusual case of tuberculosis terminating in spontaneous hemopneumo-

thorax following artificial pneumothorax. The autopsy revealed, on the anterior surface of the lung, 5 mm away from an adhesion, a small hole about 2 mm in diameter in the center of an umbilicated area that was 8 mm in diameter. This umbilicated area consisted of pleura reduced to the thinnest of tissue paper, which then sank down into the depression made by a small subpleural vomica, which it overlay and which was about the size of a cherry. The hole in the center of this area led directly into this cavity. However, the bleeding point could not be made out definitely.

CASES 7 and 8—G. A. Allan⁷ in 1925 reported two cases. Neither patient had suffered trauma and both recovered.

A man aged 20, a steel worker, was seized with a sudden sharp pain in the left side of the chest. Six hours later he had a complete collapse. Signs of pneumothorax with succussion splash, tinkle and amphoric echo were present, and dullness posteriorly. Exploratory aspiration of the chest revealed pure blood. After eighteen days the patient recovered. About ten months later a roentgenogram of his chest was taken, which was reported on by Dr. Riddell as follows: "The appearances indicate a distinct slight tuberculous lesion near the base of the left lung. There also appear to be very slight scattered lesions on the right side." The patient's history also showed that he had previously been treated for pleurisy.

A man, aged 38, had preliminary pains in the right shoulder blade for one day, which ceased if he sat down or ate a meal. The same evening he was seized with a sudden sharp pain on the right side of his chest, felt faint and almost collapsed. Examination disclosed an amphoric murmur, a succussion splash, a tympanic percussion note and shifting dullness. Heart dullness was heard 2 inches to the left of the left nipple line. Exploratory puncture of the right side of the chest revealed pure blood. Strapping of the chest gave the patient relief and he made a rapid recovery. A roentgenogram taken about five months after the attack was reported on by Dr. Riddell as follows: "The right side is distinctly less translucent than the left. The lung is not fully expanded but the space is less translucent than the lung, there is probable fluid present. I am of the opinion that tuberculosis is present in the upper half of the right lung." On the roentgen examination in both cases it seems safe to assume that both patients were tuberculous, although both recovered and were able to resume work.

CASE 9—Doria⁸ in 1928 reported the case of a young man seized with pain in the right shoulder and shortness of breath. Diagnosis of hydro-pneumothorax was made and 400 cc of air was removed. Eight days later because of increasing pain and dyspnea, 200 cc. of bloody fluid was removed. Bloody fluid was removed several times and replaced by nitrogen to prevent further bleeding. The patient recovered in about three months and was well two years later.

CASE 10—Lewis M. Hurxthal⁹ in 1928 reported the case of a young man seized with pain in the right shoulder, shortness of breath and pallor. Blood and air were found in the right side of the chest. On the third day 2,400 cc of venous like blood was removed from the chest and replaced with an equal amount of air. This procedure was repeated once, about a week later. The patient soon recovered and was well after an interval of four months.

CASE 11—Arthur H. Terry Jr.¹⁰ in 1930 reported a case in which a man aged 34 was seized with pain in the left shoulder, dyspnea and collapse. He had an attack of pleurisy five years previously. A diagnosis of hydro-pneumothorax was made. Fourteen ounces (414 cc.) of blood was removed from the left side of the chest. Three days later 530 cc of dark red bloody fluid mixed with air, was removed. The patient improved. Later, dyspnea and cyanosis returned. The patient was placed in an oxygen tent with improvement. He was discharged three months after the onset. One year later he was perfectly well. Roentgen examination revealed the chest normal.

CASE 12—A. T. Milhorat¹¹ in 1931 reported that a man aged 20, felt a sudden sharp steady pain in the left shoulder while riding comfortably in the subway. Eleven months previ-

cough he had had a pleurisy without effusion on the left side. Twelve hours after the onset of the symptoms a pain developed in the midepigastrium which spread over the entire abdomen and was most severe just below the xiphoid cartilage and in the right lower quadrant. There were signs of pneumothorax with a definite succussion splash. Rigidity of the abdomen suggested the possibility of an acute abdominal surgical lesion but after a careful and complete physical examination had been made it was felt that the abdominal pain rigidity and tenderness were secondary to the condition in the thorax. Exploratory thoracentesis of the left chest yielded pure blood which was sterile on culture. Seven thoracenteses in all were performed with the removal of from 400 to 500 cc of bloody fluid each time until after the fifth procedure when the fluid had become so viscid that only from 60 to 150 cc could be obtained. The patient was discharged fourteen weeks after the onset of his illness only a small amount of fluid remaining. Repeated sputum examinations, fourteen in all showed no acid-fast organisms. Six months after his discharge the patient had gained weight and was doing very well.

CASE 13—E. Gerard Housden and Allen Piggot¹² in 1931 reported that a man aged 44 who had had a "winter" cough for the previous nine years was seized with an exceptional attack of coughing lasting a full half hour, which exhausted him and was followed by pain in the left side of the chest

both two nights before admission and retired. While in bed, toward morning he experienced a severe pain in the right side of the chest accompanied by difficult breathing. He stated that he could not take a full breath because of the pain in his chest and he was somewhat wary of taking a full breath because of the pain caused thereby. He also stated that he had had, for the past two weeks, a severe cold accompanied by running of the nose and frequent severe cough. During this two weeks period he had not consulted a physician. The pain in the chest continued the following day, i. e., the day before admission gradually increasing in severity, especially on deep breathing or coughing, so much so that twenty-four hours after the initial attack of pain I was called and had to administer morphine. The patient was advised to go to the hospital at once but decided to wait until morning, entering the hospital approximately thirty hours after the onset of his illness.

He was unable to recall his childhood diseases except two attacks of pneumonia. Five years before he had an attack of grip which was mild and from which he fully recovered. There was no history of tuberculosis. He had never undergone an operation not even tonsillectomy.

He had a moderate appetite, with some irregularity in taking meals. The bowel movements were fairly regular, he never required a cathartic or laxative. He smoked twenty cigarettes a day.

Fig 1—Pneumothorax September 18

Fig 2—Increase of fluid September 27

Fig 3—Fluid level October 13

Two days later he resumed work but had to return home because the pain had become severe, and he went to bed at 3 30 p. m. At 8 30 p. m. he had to evacuate the bowels. Following defecation the pain became intense and he collapsed. His condition gradually became worse and the patient died the following evening. Postmortem examination revealed air and 2 pints of blood in the left pleural sac and a firm pleural adhesion attached to an emphysematous cavity at the apex of the left lung. The adhesion appeared to have been torn away from the chest wall during life and it seems quite possible that it was from the torn adhesion that bleeding took place. On removal, the left lung was found to be entirely airless. There were also present near the apex two subpleural blebs. These intercommunicated and opened out into a small thin-walled, smooth cavity. There was no caseous matter present in the cavity, and it appeared to be formed by the coalescence of many emphysematous dilatations. The authors state that they are inclined to the view that the abnormalities found in the lung post mortem indicated the source both of the pneumothorax and of the hemorrhage and that the strain caused by the violent attack of coughing and again later by defecation played a part in the production of the spontaneous hemopneumothorax.

AUTHOR'S CASE

History—W. K. a man aged 30, single, an upholsterer, admitted to the Medical Department of the Misericordia Hospital Sept 17, 1933, discharged Nov 1, 1933, took a very warm

The family history was good and there was no history of tuberculosis.

Examination—On inspection of the chest respiratory lung excursion was good on the left side but showed impeded mobility on the right side. On percussion the left chest percussion note was good with no areas of dullness or consolidation and no tympanic note. On the right there was a marked tympanic note. No dullness was noted in the right side except for a small area around the sternal margins and around the clavicle and right base. On auscultation an amphoric breath sound was heard in most of the right lung. No rales were heard in the left side of the chest and breath sounds were clear on the left side. The coin sound and succussion splash were both present on the right side.

Nutrition was good, with good muscular development. The patient stated that he lost about 5 pounds (2.3 Kg.) during the past month.

The facial expression was anxious. He was pale. There were no scars or evidence of injury on the face or head. The pupils were round, even and equal, reacting normally to light and in accommodation.

There was slight deviation of the septum.

The ears were normal.

The lips were of good color and not dry. There were no fissures or sores.

The tongue was very badly coated and furred.

There was much dental gold work and many teeth were missing. The mucous membrane of the oral cavity was intact. There were no areas of patches, sores or ulcerations.

¹² Housden E. G. and Piggot Allen. Brit. M. J. 2: 941 (Nov. 21) 1931.

In the neck there were no palpable lymph glands. The thyroid was not palpable.

The apex of the heart was clearly visible and palpable, slightly outside the left nipple line. The sounds were regular and of good force. There were no irregularities, murmurs or friction rub. The aortic second and pulmonic second sounds were both normal. Heart dullness was shifted slightly to the left, the apex one-half inch to the left of the nipple line.

There was marked rigidity of the abdomen in the right upper quadrant and the liver dullness area was markedly diminished

even on deep percussion especially on the upper border. The liver was not palpable.

There was no dysuria. There was a very faint trace of albumin in the urine. No pus or casts were found. No pain was present in either kidney area.

Examination of the skin, the bones and joints and the glands gave negative results.

The reflexes were normal to stimuli.

The impression and provisional diagnosis were pneumohydrothorax.

Fig 4—Appearance of chest October 21

A roentgenogram (fig 1) taken on the day of admission showed a complete pneumothorax on the right side with a complete collapse of the lobes of the right lung. The mediastinal shadow, including the heart, was shifted slightly to the left and the left lung fields showed a diminution in the amount of aeration, there was considerable amount of fluid in the right base.

The roentgen diagnosis was complete pneumothorax of the right side of the chest, with hydrothorax.

Treatment and Course—The patient was given codeine for the cough and pain, one-half gram (0.03 Gm) every four hours. His temperature remained around 100 F and his pulse varied from 90 to 100 and at no time during his stay in the hospital did his temperature exceed 101 or his pulse 100. Enemas were given for evacuation and in spite of this, defecation materially increased the pain in the chest, which was felt mostly in the region of the right shoulder and down the right arm. The following day September 19, the patient had less pain and was able to sleep several hours that night. His condition did not change materially and on September 27 a second roentgen examination was made (fig 2), which still showed complete collapse of the right lobes, the only difference from the previous examination was the increase in the amount of fluid in the right thorax. The left lung fields still remained clear.

As the patient's condition was comparatively good and as the true character of the fluid within the chest was not suspected up to this time it was decided to treat him expectantly. A third film taken October 13 (fig 3) demonstrated the right lung to be more than half aerated with the fluid level extending up to the third rib anteriorly. The heart and trachea showed a moderate displacement to the left side.

The diagnosis was hydropneumothorax, with evidence of more fluid at this examination.

It was decided to do a thoracentesis, and on October 14, under procaine hydrochloride anesthesia, 420 cc of bloody fluid was removed from the right side of the thorax, specimens of which were sent to the laboratory for guinea-pig inoculation, for smears and for culture. The withdrawal of fluid had to be interrupted on reaching 420 cc. because of an attack of syncope. The laboratory examination of these specimens revealed many red blood cells on direct smear, with only a few

scattered lymphocytes and polymorphonuclear leukocytes. No bacteria were seen. A culture was sterile after seven days. The results of guinea-pig inoculation were reported on November 25. Fragments of the liver and the spleen removed from a guinea-pig that had been injected five weeks previously with bloody fluid from the thorax gave no gross evidence of tuberculosis. Sections taken through the liver and spleen showed no evidence of tuberculosis.

The blood Wassermann reaction with alcoholic antigen and with cholesterinized antigen was negative.

Sputum, obtained with great difficulty, was negative for tubercle bacilli on two separate examinations.

The patient rallied quickly from his syncope but felt fairly weak for twenty-four hours. He was given hot liquids and external heat. A blood count October 18 showed hemoglobin 82 per cent, red blood cells 5,200,000, white blood cells 14,000 polymorphonuclears 58 per cent lymphocytes 32 per cent. No abnormal cells were seen. October 20 a fluoroscopic examination showed the fluid level up to the second interspace in the right side of the chest. On inspiration the fluid rose to the height of the first interspace. It was determined to do a further thoracentesis and accordingly on October 21, with procaine hydrochloride anesthesia, 800 cc. of bloody fluid was aspirated from the right side of the thorax. The film immediately following the aspiration (fig 4) demonstrated a hazy shadow involving the lower half of the right lung field, which could be the result of a thin layer of fluid or of a moderately thickened pleura. There was no evidence of a new growth of either lung field. The mediastinum and heart were in the midline at this time.

Within the next few days the patient had slight pain in the right chest and examination disclosed audible friction sounds anteriorly and moderate dullness at the right base posteriorly which was interpreted as being due to a thickened pleura and some fluid. The patient's condition gradually improved until November 1, when he was discharged from the hospital for further convalescence at home. Examination at the hospital, just previous to his discharge still showed friction sounds on the right side and slight dullness at the base posteriorly.

A subsequent chest film which was taken November 28 (fig 5), demonstrated the lung fields to be clear with no evidence of a tuberculosis or pneumonic process on either side. The heart was small, and globular in type.

The roentgen examination gave results within normal limits. There was no evidence of the previously reported hydropneumothorax (hemopneumothorax) of the right lung.

In May 1934, six months after his discharge and seven and one-half months after the onset of illness, his condition was very satisfactory. He has been working at his trade as an upholsterer since the first of January and feels no discomfort. He has gained about 8 pounds (3.6 Kg).

Fig 5—Lung fields clear November 28

COMMENT

This case, as well as the thirteen reported previously, is of interest because of the hemorrhage accompanying the pneumothorax. Pitt in his report cites Pagenstecher's experiments, which showed that the pleurae, similar to the blood vessels, are capable of keeping contained blood fluid for a long time and that the production of clotting is, similarly to that of thrombosis,

often started by a lesion of the wall. Two hours after blood was injected into the pleural cavity experimentally it was almost always fluid, after six hours there was a fluid resembling blood in appearance, but it would not clot. No inflammatory changes were induced. The pleura therefore can keep the blood fluid but not unaltered. A considerable portion of the fluid is absorbed. In his experiments blood in the pleura was absorbed in a fortnight, but Wintrich concluded that a traumatic hemothorax required from six to twenty-eight days to absorb.

Pitt, in the same article, cites Blumenthal,¹³ who in 1868 collected fifty-five reported cases of nontraumatic hemothorax, which he classified as follows: (1) tubercle, nineteen cases, (2) secondary to other diseases fifteen cases, (3) primary, nine cases, (4) malignant disease of the pleura, twelve cases. An examination of the notes shows that there was an effusion of blood in only three of the so-called primary cases and in five of the malignant, and that in almost all the others the fluid was only stained with blood.

Pitt further classifies pneumothorax as follows:

1 Punctured wounds of the thorax. Laceration of the lung or bronchi by compression of the chest or by fractured ribs. A punctured wound of the lung will not produce hemothorax unless an important vessel is injured but the smallest puncture may be sufficient to produce a pneumothorax.

2 Perforation of tuberculous cavities. This is by far the most common cause.

3 Empyema opening into the lung.

4 Abscess of the chest wall opening inward.

5 Perforating gastric ulcer, with a subdiaphragmatic abscess, burrowing upward.

6 Gangrene of the lung.

7 Acute abscess of the lung.

8 Bronchiectasis.

9 Pulmonary apoplexy with gangrene.

10 Hydatid.

11 Rupture of an emphysematous bulla. This has occurred in men apparently perfectly healthy and has often ended in recovery. Fraentzel¹⁴ also has pointed out that the rupture may occur as the result of violent physical effort, in one case as the result of attempting to lift a heavy cask, and in a case of Findlay's after attempting to stoop down backward.

12 Tracheotomy. This occurs when the operation does not relieve the obstruction or when the tube has been accidentally pushed down in the connective tissue to one side of the trachea or even when the incision is a very low one. An emphysema takes place into the connective tissue of the anterior mediastinum and then a rupture occurs, allowing the air to pass into the pleura.

13 Perforations of the esophagus.

Having considered all the possible causes of both hemothorax and pneumothorax per se I will now examine the four cases of hemopneumothorax that came to autopsy, among the previously reported thirteen cases, namely, Pitt's, Rolleston's, Heise and Krause's, and Housden and Piggot's cases, to see whether any conclusion can be drawn from these as to the probable factors at work in the production of hemorrhage besides pneumothorax and collapse of the lung. Three of these showed a torn pleural adhesion and a torn or ruptured emphysematous bulla, Rolleston's case being the only one that at autopsy showed no definite cause for either the pneumothorax or the hemorrhage into the pleural cavity.

Housden and Piggot, in the discussion of their case, emphasize the fact that they incline to the view that in Pitt's case and Krause and Heise's case, as well as their own case, the torn pleural adhesion and ruptured emphysematous bulla accounted for both the hemorrhage and the pneumothorax.

One other significant fact stands out clearly in all the fourteen cases, the present one included, and that is that all these victims of hemopneumothorax were males, a satisfactory explanation for which is lacking.

CONCLUSIONS

1 In a case of spontaneous hemopneumothorax, with recovery, in a young man, and thirteen collected cases from the literature, no definite etiology is demonstrable, but three of the previously reported cases point strongly to a torn pleural adhesion and a ruptured emphysematous bulla or bleb as the cause.

2 All cases reported, including the present one, occurred in the male.

3 Aspiration of the blood is the procedure of choice.

4 The condition is exceedingly rare.

333 East Eighty-Seventh Street

DIPHTHERIA OF THE PENIS

MAXWELL P. BOROVSKY, MD

CHICAGO

Diphtheria of the penis is a rare disease. A careful review of the literature reveals none reported at as early an age as my patient.

In 1930 Hoyne and Levy,¹ in reporting a case of diphtheria of the penis in a 7 year old boy, reviewed the literature, which disclosed only fifteen similar reports.

The first cases of diphtheria of the penis were reported in 1897 and, strangely enough, by three different observers in a period of a few months.

Munn,² in February 1897, reported three cases of this disease. One was in a 5 year old boy who developed the condition following circumcision. There were no cultures taken, and diphtheria antitoxin was not administered. The infection cleared up under local treatment. Another was in a 9 months old infant who was circumcised, following which a membrane developed at the site of operation which on culture showed Klebs-Loeffler bacilli. The mother was then suffering from faucial diphtheria. Thirty-five hundred units of diphtheria antitoxin was administered to the baby, but it died of toxemia and generalized hemorrhages. His third case occurred following circumcision in a 3 months old baby whose mother and brother had diphtheria. One thousand units of antitoxin was administered, with recovery.

In October of the same year Post³ reported a case of diphtheria of the penis in a young adult whose wife, child and brother-in-law had diphtheria. No antitoxin was given to this patient, and ciliary paralysis of both eyes and postdiphtheritic paralysis of all four extremities developed.

Later that year, November 1897, McCollom⁴ reported two cases. One was in a 4 year old boy who had scarlet fever and nasal diphtheria, diphtheria of the prepuce

14 Fraentzel in Ziemssen's Cyclopaedia of the Practice of Medicine 4:739.

developed. Cultures were positive for Klebs-Loeffler bacilli, but antitoxin was not administered. His second case was in a 1½ year old boy with laryngeal diphtheria, in whom diphtheria of the penis developed although he had been circumcised several months before.

The next case appeared in the literature ten years later, when O'Brien,⁵ in October 1907, reported the occurrence of diphtheria of the glans penis in a 13 months old baby three days following circumcision.

Fig. 1—Appearance of penis seventeen days after circumcision showing diphtheritic membrane.

The same year Beatty⁶ reported diphtheria of the glans penis in a 3 year old boy with faucial and laryngeal diphtheria who had been circumcised four weeks previously.

Riva-Rocci,⁷ in the same year, described two cases of diphtheria of the penis in two boys, aged 1 and 4 years. The former was in contact with a sister who had diph-

theria. Both recovered following the administration of diphtheria antitoxin.

In 1912 Kolmer⁸ reported two cases following circumcision, one in an 18 months and another in a 2 year old boy. Both recovered following the administration of diphtheria antitoxin, 7,200 and 4,800 units respectively.

Prinzing¹¹ in 1928 reported the occurrence of diphtheria of the penis in a man, aged 28, whose wife had a positive vulval and throat culture.

Vasile,¹² in the same year, told of a case in a boy, aged 16 months who had not been circumcised. Thirty thousand units of diphtheria antitoxin was administered in two injections.

In 1929, Schmidt¹³ reported a diphtheritic infection of a wound of the penis and scrotum in a man.

Hoyne and Levy,¹ in 1930, reported the occurrence of diphtheria of the glans penis in a 7 year old boy, circumcised in infancy, who also had oral and nasal diphtheria.

In 1931 Molteni and Casazza¹⁴ reported a diphtheritic infection of the glans penis in an infant.

A total of eighteen cases of penile diphtheria have been reported in the medical literature, fifteen in children and three in adults. One half were confirmed by culture and many patients recovered without the use of diphtheria antitoxin, so that the authenticity of the presence of the specific disease might be questioned. That patients with diphtheria may recover without antitoxin is not doubted, but one speaks more positively about a case if the organism has been recovered and the specific reaction to antitoxin is observed.

REPORT OF CASE

S. C. born at the Presbyterian Hospital, Sept. 2, 1932, was the first child of normal, healthy parents. The birth weight was 5 pounds 14 ounces (2,666 Gm). Delivery was normal and the breathing spontaneous. The progress of the baby was retarded by the deficiency of breast milk and by frequent stools. Protein milk with a preparation of maltose and dextrin was prescribed, and the weight at 10 days was 5 pounds 13 ounces (2,638 Gm). Evaporated milk feedings were prescribed for home use and the breast milk feedings were dispensed with.

Summary of Reported Cases of Diphtheria of the Penis

Author and Year	Under 1 Year	1 to 14 Years	Adult	Culture	Antitoxin	Circumcised	Other Diphtheritic Foci
Munn ² 1897		5 years		None	None	10 days previously	
Munn ² 1897	9 months			Klebs-Loeffler bacilli +	3,500 units	Few days previously	Mother
Munn ² 1897	3 months			None	1,000 units	Few days previously	Mother and brother
Post ³ 1897			+	None	None		Wife child and brother in law
McCullom ⁴ 1897		4 years		Klebs-Loeffler bacilli +	None		Nasal
McCullom ⁴ 1897		1½ years					Laryngeal
O'Brien ⁵ 1907		13 months				Early in life	
Beatty ⁶ 1907		3 years				3 days previously	Faucial and laryngeal
						4 weeks previously	Sister
Riva-Rocci ⁷ 1907		1 year		Klebs-Loeffler bacilli +	Three injections	No	
Riva-Rocci ⁷ 1907		4 years			Two injections	No	
Kolmer ⁸ 1912		18 months		Klebs-Loeffler bacilli +	7,200 units		
Kolmer ⁸ 1912		2 years		Klebs-Loeffler bacilli +	4,800 units		
Cochrane ⁹ 1921		3 years					
Bode ¹⁰ 1921		6 years					Faucial
Prinzing ¹¹ 1928			28 years	Klebs-Loeffler bacilli +			Wife
Vasile ¹² 1928		16 months		Klebs-Loeffler bacilli +	20,000 and 10,000 units	No	
Schmidt ¹³ 1929			+	Klebs-Loeffler bacilli +			
Hoyne and Levy ¹ 1930		7 years		Klebs-Loeffler bacilli +		Yes	Oral and nasal
Molteni and Casazza ¹⁴ 1931	+	Further information not obtainable					
Reported here							
D. R. ..	+			Klebs-Loeffler bacilli +	5,000 units	5 days previously	None
Rosenblum	+			Klebs-Loeffler bacilli +	10,000 units	3 weeks previously	None
Borovsky	+			Klebs-Loeffler bacilli +	5,000 units	10 days previously	None

The next reports appeared in 1921, Cochrane⁹ reporting a case in a 3 year old and Bode¹⁰ in a 6 year old boy. The latter patient also had faucial diphtheria.

Circumcision was performed at the hospital on the eleventh day under strictly aseptic conditions by a mohel who wore a mask and rubber gloves during the operation. Two days later he called at the home to dress the wound.

About ten days later the mother reported that the infant cried considerably and seemed to have 'colic'. The crying was

later discovered to be due to painful urination caused by the sealing of the meatus. Telephone advice was given but the symptoms persisted and the patient was first seen at home fifteen days after the circumcision.

A necrotic, sloughing edematous area was seen at the site of circumcision with a thin grayish film over the glans (fig 1). Cellulitis was diagnosed at this time and hot dressings were prescribed. The infected area showed no improvement under this management, and the following day sixteen days after the circumcision, a culture on Loeffler's medium was taken and a pure culture of diphtheria bacillus was recovered.

Five thousand units of diphtheria antitoxin was then given intramuscularly and all other treatment discontinued. Two days later the membrane began to wrinkle and loosen from its base. The following day, four days after the antitoxin administration, the membrane was removed in toto (fig 2) and 1 per cent yellow mercuric oxide was applied.

Urination now became painless and the general condition of the infant improved. Bismuth formic iodide powder was then applied locally until complete healing resulted. October 20 thirty seven days after the operation.

There was practically no temperature reaction produced by the infection or by the antitoxin administration. The weight Oct. 13 was 7 pounds 6 ounces (3,345 Gm.) November 10 9 pounds 10 ounces (4,366 Gm.) The general condition improved regularly.

Active immunization against diphtheria with three injections of toxoid at monthly intervals was instituted at 4 months of age. A Schick test performed three months after the last injection, proved negative.

COMMENT

It is more than coincidence that in 1928 the same mohel had performed a circumcision that resulted in a case of diphtheria of the penis five days after the operation. The smears were positive for Klebs-Loeffler bacilli, and 5,000 units of diphtheria antitoxin was administered in two doses. Prompt recovery resulted.

Two other such occurrences are recalled by the Chicago health department authorities, but the records are no longer available.

This mohel had previously been discovered to be a diphtheria carrier and had been quarantined and treated a few years ago.

He was released after negative nose and throat cultures had been obtained.

He recently performed a circumcision on a 3½ weeks old premature baby in whom a diphtheritic infection of the penis developed that resulted fatally. The case was seen three weeks after circumcision by Dr. Philip Rosenblum, who

Fig. 2—Appearance four days after administration of diphtheria antitoxin.

has kindly consented to my report of this case along with my own. Cultures from the penis and from the nose were positive for Klebs-Loeffler bacilli. Ten thousand units of diphtheria antitoxin was administered, but the baby died of myocarditis and bronchopneumonia.

Circumstances point to the conclusion that this man has been directly responsible for the development of at least five cases of diphtheria of the penis following circumcision. As a result several hospitals have prohibited his operative work in their institutions.

SUMMARY

1 Only four cases of diphtheria of the penis have been reported in the literature occurring under 1 year.

2 The personally observed patient is the youngest one on record.

3 Information concerning two other authentic cases, one in the new-born period and one at 6 weeks of age, was received by personal communication.

4 Two other cases are recalled by the Chicago health department authorities.

5 In all five cases (three absolutely authentic, two reported from memory by Chicago health department authorities), circumcision was done by the same mohel.

6 Transmission of the diphtheritic infection probably took place in my case during the change of dressings at home two days after the circumcision. The mask and rubber gloves worn during the operation would probably prevent the infection at that time.

PRIMARY ENDOMETRIOSIS OF THE URINARY BLADDER

REPORT OF ONE CASE

ERLE HENRIKSEN, M.D.
BALTIMORE

During the past decade the gynecologic literature has become heavily laden with discussions of the theories as to the nature and pathogenesis of endometriosis. Owing to the rarity of vesical endometriosis, a report of this case would seem to be warranted. Thirty cases of endometriosis of the urinary bladder have been found in the literature, but of these only twenty-one belong to the so-called primary group.

The genesis of endometriosis, as well as its mode of dissemination, is still an unsettled question. Briefly summarized, the more important of the theories may be arranged as follows:

1 Origin from the normal endometrial tissue of the genital tract.

(a) Proliferation in continuity through the walls of the uterus and tubes (Cullen,¹ 1896).

(b) Lymphogenous metastasis (Halban,² 1924).

(c) Propagation by retrograde menstruation (Sampson,³ 1921).

2 Origin from embryonic remnants in the genital tract.

(a) The wolffian ducts (von Recklinghausen,⁴ 1895).

(b) The müllerian ducts (Kossmann,⁵ 1897).

3 Metaplasia of the serosal endothelium (Iwanoff,⁶ 1898, Meyer,⁷ 1924).

Experienced observers have adduced evidence in support of most of the theories mentioned. Most gynecologists, however, believe that the question of the pathogenesis of endometriosis is not yet settled and that the mechanism is probably not always the same.

ENDOMETRIOSIS—HENRIKSEN

JOUR. A. M. A.
APRIL 20 1935

Cullen's theory of mucosal invasion has been accepted as an adequate explanation for uterine adenomyomas. The view of an origin by metastasis through the lymph spaces has few supporters. Sampson's implantation theory is probably the most widely accepted of all, especially in explanation of the origin of peritoneal and

including the present case, have appeared in the literature. The shallowness of the space of Retzius may account for the rarity of endometrial implants in this portion of the pelvis as compared with their relative frequency in the deep culdesac of Douglas. It is not uncommon to find endometrial implants at the base of the uterovesical peritoneal reflection following pelvic operations, though in such cases the walls of both the uterus and the bladder are usually invaded (Sampson). I feel that the term "primary vesical endometriosis" should be limited to those cases in which no demonstrable contiguity with the uterus, fallopian tubes or ovaries is present and in which there has been no surgical trauma of the bladder wall or its peritoneal reflection. In conformity with this criterion I shall present the following case, with illustrations for no continuity could be demonstrated between the uterus and the bladder and, although there had been a previous pelvic operation, the bladder peritoneum had not been traumatized.

REPORT OF CASE

M. B., a woman, aged 27, had an appendectomy through a McBurney's incision at the age of 16 years. Bilateral salpingectomy was done for "pus tubes" without the usual suspension of the uterus by suturing the round ligaments over the tubal sites at the age of 18 years. The latter operation was performed nine days after the onset of the previous period through a midline incision. The operator noted that the tubes were easily removed and no attempt was made to suspend the uterus. The general health was excellent until one year before admission, at which time a dull aching pain appeared in the left lower quadrant, this was not aggravated by menstruation and failed to respond to the usual forms of conservative palliation. Two months before, severe pain on micturition developed following the cessation of the menstrual period but no hematuria was noted. However the urinary symptoms became more marked and included dysuria and diurnal and nocturnal frequency. Catheterized specimens of urine unfortunately collected between the periods were negative for red blood cells. Urinary antiseptics alleviated the symptoms. On bimanual examination a small movable mass could be outlined anterior to the fundus

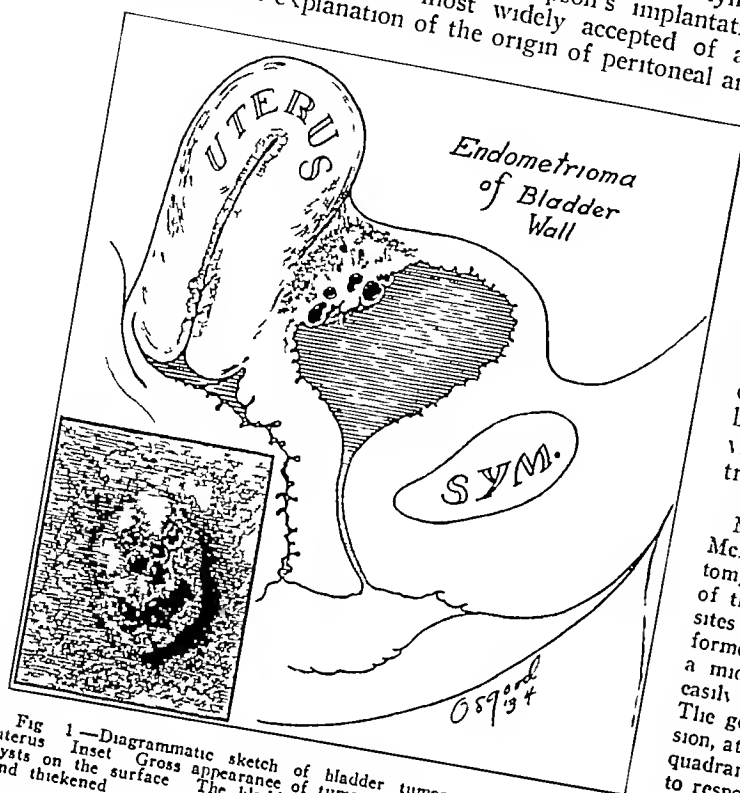

Fig 1—Diagrammatic sketch of bladder tumor in relation to the uterus. Inset Gross appearance of tumor with the characteristic bluish cysts on the surface. The bladder mucosa about the tumor is injected and thickened.

Fig 2—Nests of endometrial tissue scattered through the bladder wall as seen in the low power field. Dilated endometrial glands lined by columnar epithelium and small nests of bladder epithelium remain on the surfaces of the cysts.

this was moderately tender and seemed pedunculated. It was thought to be a small subserous myoma of the uterus. Both ovaries were normal in size and limited in mobility. Unfortunately a cystoscopic examination was not made (1) because the possibility of a bladder tumor was not considered and (2) because the several catheterized specimens of urine had been negative on microscopic examination. The abdomen was entered through a low midline incision, the uterus was normal in size in good anteposition and movable and the surfaces were smooth. The cornual scars were well healed and free of adhesions. The ovaries were normal in size

ovarian endometriosis. The serosal theory of Ivanoff, Meyer⁸ and Novak⁹ is supported by many. It offers the confused student of the subject an acceptable genetic explanation for many of the heterotopic endometrial nests. Though transitional stages between the peritoneal endothelium and the uterine mucosa have been observed, the segregation of endothelial cells to form an endometrial tumor has not been proved. To presuppose that the metaplastic aptitude of the peritoneal endothelium accounts for the formation of both the epithelial and the stromal elements assumes a highly specific organoid activity not present elsewhere. At present there is a tendency to explain heterotopias as due to anomalies of cell differentiation resulting from changes in cellular environment. If this is normal, the differentiation is normal, if the influences are abnormal, the differentiation is abnormal. As to the genesis of primary vesical endometriosis, I feel that von Recklinghausen's theory of wolffian duct remnants or Kossman's of mullerian duct remnants is the most likely. Because of its close similarity in gross appearance to malignant growths of the urinary bladder, the possibilities of vesical endometriosis must be considered in cases of hematuria, especially when associated with dysuria and increased frequency of urination, occurring in sequence.

In 1921 Starr Judd⁹ reported the first case, and to date twenty-one cases of primary vesical endometriosis,

⁸ Novak Emil. Significance of Uterine Mucosa in Fallopian Tubes with Discussion of Origin of Aberrant Endometrium. *Am. J. Obst. & Gynec.* 12: 484 (Oct.) 1926. *Pelvic Endometriosis* *ibid.* 22: 826 (Dec.) 1931. Personal communication to the author.

⁹ Judd E. S. Adenomyoma Presenting as a Tumor of the Bladder. *S. Clin. North America* 1: 1271 (Oct.) 1921.

and were easily released from thin bands of fibrous adhesions. There was no suggestion either of peritoneal or of ovarian endometriosis. Lying anterior to the uterus (fig. 1) and completely covered by the peritoneal reflection was a small palpable mass approximately 4 cm in diameter. The bladder peritoneal reflection was easily separated from the uterus and the mass was found to be within the bladder. The bladder was entered and the tumor mass was exposed. The bladder mucosa about it was slightly injected but otherwise normal in appearance. The mass was excised with a narrow margin of healthy bladder tissue and the wound tightly closed in three layers with plain catgut sutures. A mushroom catheter number 14 was left in the bladder for ten days. The postoperative course was smooth and when discharged on the fifteenth day the patient voided 350 cc of urine without hesitancy or discomfort. One month later she reported that she had had a normal menstrual period and had experienced neither abdominal nor urinary discomfort.

SYMPTOMS

In a careful review of most of the reported cases a fairly constant symptom complex presents itself, although a few have been asymptomatic from a urinary standpoint. In the majority of the cases frequency, dysuria and hematuria appear several days before menstruation persist during the flow and generally continue for a day or even a week after its cessation. The course of the disease is chronic starting first with a slight discomfort which is constant but not aggravated by the menstrual periods, though later the clinical picture changes and is somewhat as follows:

Increased frequency of urination, both by day and by night is the most common complaint and as a rule disappears completely between the periods.

Dysuria varies but usually occurs at the end of micturition, more as a sense of discomfort than as actual pain.

Hematuria because of its microscopic nature is rarely noted by the patient and is present only during menstruation or just preceding it.

There is a marked variation in the severity of the symptoms, depending naturally on the size and topographic location of the tumor within the bladder, as well as the degree of tissue reaction during the menstrual period. When the ureters are encroached on, there is the added symptom suggesting kidney involvement. However, even in case of ureteral obstruction the symptoms appear in a certain constant order and are sequential in appearance and degree of severity. This triad, when associated with the bimanual palpation of a tumor mass, is practically pathognomonic of vesical endometriosis. In the absence of the triad it is important to differentiate this condition from carcinoma, cavernous angiomas and bladder varicosities.

AGE

The youngest patient was 19 years of age. There is apparently, however, a predilection for the decade between 35 and 45 years. Except for the one case reported by Whitehouse,¹⁰ all have occurred during menstrual life.

LOCATION

As a rule, the tumors are located within the floor of the bladder, just above or between the ureters with a peculiar predilection for the right side. They are rarely found in the vertex and though they may involve the trigon, the involvement is through extension. The size of the tumors is fairly constant being generally between 2 and 4 cm. They usually present a distinctly nodular surface.

TREATMENT

The treatment of this tumor cannot be prescribed dogmatically. The size, the topographic location, the age and the general condition of the patient are the deciding factors as to which of the two possible therapeutic procedures is best suited.

1 Complete excision is the method of choice in young women desirous of children and in whom the margin of bladder tissue safety is sufficient.

2 Castration is done, either by operation or by irradiation, in patients near the menopause or in whom the growth is too extensive for excision, or when the general condition of the patient contraindicates surgical measures.

SUMMARY

1 The lesion usually presents a symptom complex recognized by its cyclic relation to the menstrual period and consisting of increased frequency of urination, dysuria and hematuria.

2 The mode of treatment is dependent on the age of the patient, the size and localization of the tumor, and the general condition of the patient.

3 Since there are cases presenting an atypical picture this tumor may easily be mistaken for malignant lesions of the urinary bladder.

Clinical Notes, Suggestions and New Instruments

POSTURAL TREATMENT OF TYPANITES

WILLIAM SNOW, M.D. AND CHARLES S. B. CASSARA, M.D.
NEW YORK

The presence of gas in the small bowel of infants observed in routine roentgen examination for various conditions, has been noted for some time. Its cause and significance have not been understood. The solution of this problem was found by placing infants in the semi-inclined position.

In animals in the all-four position, the entrance of the esophagus into the stomach is on a higher level than the exit through the pylorus. When they swallow gas with food it collects above the food and fluid secretions and can easily escape through the esophagus. Since infants lie on their backs for the most part especially new-born infants in the hospital, the swallowed gas rises into the distal or pyloric end of the stomach where it is trapped by fluids. It therefore cannot escape through the esophagus and must be forced through the pylorus into the small intestine.

To prove this assumption fifty new-born infants were roentgenographed in this manner.

The first day they were taken from the cribs where they had been in the usual recumbent posture and roentgenographed. The second day they were roentgenographed after having been kept in the semi-inclined position for twenty-four hours. The semi-inclined position should cause the gas bubble to rise into the cardiac portion of the stomach so that it might escape through the esophagus freely. Of the fifty cases examined, twenty-five showed the presence of gas in the large and small intestines on the first day of the examination. These twenty-five cases showed disappearance of the gas in the small intestine by the postural treatment in twenty-two cases. The three failures were probably due to the fact that it was difficult to maintain the inclined position in all cases.

Routine examination for a variety of conditions such as occur in a hospital rarely showed the presence of gas in the small intestine in children over 3 months of age. This is probably due to the fact that children roll from side to side at about this age. Since it is well known that infant colic frequently

¹⁰ Whitehouse, H. B. Endometrioma Invading Bladder Removed from Patient Who Had Never Menstruated. *Proc. Roy. Soc. Med.* 15: 1926.

From the first Obstetric Division of the Bronx Hospital and from the Harlem Hospital.
Material on exhibition at the Gastro-Intestinal Fortnightly Symposium at the New York Academy of Medicine in October 1934.

disappears after this age, the possibility suggested itself that the gas forced into the small bowel was an important factor if not the sole cause in most cases of infant colic. In a number of cases in which infants were doing well and gaining weight it was found that colic disappeared by keeping them in the inclined position or on the abdomen. The latter procedure is an old method used by grandmothers for centuries. Its rationale is now explained.

The gas distention that occurs postoperatively and in pneumonia may be dependent on the same factors as described. In fact, it is suggested that Fowler's position is probably beneficial mainly because of the same conditions.

CONCLUSIONS

1. Fifty per cent of new-born infants showed distention of the small bowel with gas.
2. Past 3 months of age the gas disappears from the small bowel in healthy infants.
3. The gas may be made to disappear from the small intestine by placing the infant in the semi-inclined position so that gas in the stomach may not be trapped at the pylorus and then forced into the small intestine.
4. Gas distention in pneumonia and in postoperative cases may possibly be explained in the same way.

A TREPHINE MODIFIED TO SECURE BONE MARROW (STERIL) BIOPSIES

E. L. TUOHY, M.D. AND M. G. GILLESPIE, M.D.
DULUTH, MINN.

The trephine here devised and illustrated as to its parts (fig. 1) is modified from the various puncture needles (Ghe dini, Arinkin, Seyfarth and others) long suggested to get marrow specimens safely both for histologic embedding and for smears for routine staining. The sternum is ideally adapted as a source both because of ease of access and because of its persistent functional activity throughout life. The ribs are equally active but not so simple to approach. Isaacs has correctly criticized simple needle puncture methods as really yielding mixtures of marrow elements 'washed out' with traumatically induced blood flow. Thus one has blood with certain marrow admixtures. We have found this true, especially when the marrow system is inactive. Ordinary chronic myeloid leukemia, however, yields needle puncture material so readily that smears so closely resemble ordinary blood smears as to make the observer feel that he has tapped an actual vessel or blood space.

It is obvious that sections of fixed marrow tissue while useful can never give the desired morphologic detail essential to develop the diagnostic and therapeutic guidance that this pre-

Fig. 1—Parts of the instrument

eminent hematopoietic source material (erythrocytic, granulocytic and thrombocytic) promises.

This instrument is easy to use. The biopsy is painlessly accomplished under simple procaine hydrochloride anesthesia and a 0.5 cm. scalpel incision through the skin brings the instrument down to the periosteum. It yields a round marrow segment without either hemorrhage or blood admixture. The tip of this plug permits the making of from three to five delicate touch smears. Stained either with double strength Giemsa or ordinary Wright's stain, beautiful diagnostic preparations are available. The present superactivity in the domain

of hematology renders studies of bone marrow in all cases of low leukocyte or platelet counts, with or without purpuric or ulcerative tendencies as well as all anemias of doubtful origin or classification, a fruitful field for investigation.

STRUCTURE OF THE INSTRUMENT

This instrument consists of three parts. The first part is a trephine. This is made of chrome vanadium steel. It measures 5.5 cm. in length and has an inside diameter of 4 mm. and an outside diameter of 5 mm. Thus it is readily seen that the

Fig. 2—Biopsy specimen magnified four diameters

metal is very thin. On the terminal end of the trephine is a series of fine teeth. The proximal end is fitted with a handle-like effect in which the instrument can be grasped and readily turned. On one side of the instrument beginning at the terminal portion there is a millimeter scale, which runs up to 3 cm. The proximal lumen will just fit a Luer syringe. The second portion of the instrument consists of a stilet that just fits the inside lumen of the trephine. The terminal end of the stilet has a blunt faceted (three facets) surface. The third portion consists of a long screwlike slender nail. Only the terminal end for a distance of about 3 mm. has this screw-like effect.

TECHNIC

The field of operation is prepared in the usual manner with the use of iodine and alcohol, a site over the sternum is selected in the interspace between the second and third ribs.

Fig. 3—Roentgen appearance of the biopsy specimen

A small fine hypodermic needle being used first the skin and subcutaneous tissue and then the periosteum are infiltrated well with procaine hydrochloride solution. It is then best to wait for from five or ten minutes, an incision is then made over this site about 1 cm. in length. Dissection is carried down to the sternum in an effort to divide the subcutaneous tissue and the tendinous insertions on the anterior aspect of the sternum. The trephine with the stilet inserted is then introduced through the incision and with a boring motion is carried down to the periosteum. The stilet is then withdrawn and the screw is inserted through the trephine and bored into the anterior plate of the sternum until it holds firmly. The trephine is turned slowly and pressure is applied. The trephine will be not only felt but actually heard as it cuts through the anterior plate of the sternum. When the trephine is through the lamella of bone there is a certain give, and a few more turns are taken and the instrument (the trephine and the screw) are withdrawn together. It will be found that the plug of the sternum and the bone marrow will be attached to the screw. The screw is removed, the specimen is gently stroked two or three times over one or two glass slides and the specimen is then placed in 5 per cent formaldehyde solution. Sections for microscopic study may be prepared if desired.

There is very little bleeding and the wound edges usually fall together or, if not they can be brought together with adhesive plaster, or a skin clip and a dressing may be applied. As a rule, there is very little distress during or after this procedure.

Special Article

GLANDULAR PHYSIOLOGY AND THERAPY

THE TESTIS HORMONE

CARL R. MOORE, Ph.D.
CHICAGO

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues. When completed the series will be published in book form.—LW

The testicle exercises at least two biologic functions of utility in the organism, the primary of which is maturation of germ cells and the secondary the secretion of one or more substances known as the testis hormone. The primary function is much the older and is exercised not only in vertebrates but in invertebrates as well. Hormone secretion, however, appears to be restricted to the vertebrates and to have undergone a gradual increase in complexity, it is on the accessory organs of reproduction that the influence of the testicular hormone is exercised.

In some lower fish the sex cells are merely liberated from the gonad into the general body cavity, making their escape through abdominal pores to the outside to meet the female cell, no specialized duct is maintained for their passage. The majority of fish and amphibia utilize the wolffian duct for carrying spermatozoa away from the testicle, the functional condition of the duct is developed periodically as the germ cells mature in the testes. In still higher forms this wolffian duct, or vas deferens, becomes more complicated, it may be coiled into an epididymis-like structure and produce evaginated pocket-like glandular organs (seminal vesicles) which contribute secretions. Additions include also the establishment and maintenance of various types of intromittent organs for the transfer of semen to the female genital passages for internal insemination. In mammals many structures such as the prostate gland, seminal vesicle, Cowper's gland and others and the intromittent, or copulatory, organ make of this system a rather complicated, correlated set of structures whose functional state must be established at the proper time for storing, maturing and transporting germ cells. In general the testes of vertebrates appear to function for only a limited period once each year when the germ cells are matured and hormone secretion induces a functional condition on the part of all accessory reproductive structures, hormone secretion is therefore closely correlated with the primary testicular function of germ cell production.

Some few vertebrates, including man, do not have a strictly limited annual reproductive period, in these, germinal cells are matured during all seasons of the year. In this group hormone secretion is likewise continuous, and the accessory organs are maintained in a functional condition at all times.

It is my aim in this section to present some of the general phases and particular details of the testis hormone and to discuss some of the principles and possibilities of its clinical application. The experimental animal must be depended on for presenting the various aspects, since knowledge of the manifestations of hor-

mone deficiencies in man, of methods of detecting the presence or absence of the hormone, or of its utility in the species is so limited as to be of little value.

METHODS OF DETECTION

The tardiness with which the hormone of the testicle was successfully extracted has been due first to the lack of proper methods of revealing it, and, secondly, to the relatively low yield of the hormone from extraction of this organ. The most frequently used test is the growth of the comb of the castrated cock, or capon. The work of many individuals has revealed that castration of the cock entails the immediate regression of the comb and that a testis graft or the injection of extractives from cryptorchid testicles of pigs rebuilds the comb of capons to the cock type.¹

(a) The capon comb growth test, applied most often to the single comb leghorn fowl, depends on the growth response of the comb of a capon following subcutaneous injections. It has been utilized in many laboratories² with slightly different procedures, as employed by Gallagher and Koch, the response is determined by the increase in length plus height of the comb measured in millimeters. The bird unit of hormone has been defined by them as the amount of material injected over a period of five days (daily injection) required to cause an increase in the comb (length plus height) of from 3 to 7 mm, by the sixth day, in at least five out of ten injected capons.³

Mammalian tests thus far employed have depended on the responses of different parts of the accessory reproductive organ complex. External manifestations have proved to be impracticable, though attempts have been made to utilize such factors as body size, conditions of the hair coat, and fat deposition.

(b) The spermatozoon motility test, one of the first mammalian tests to be employed for detection of the testicular hormone, depends on the fact that spermatozoa in the epididymus of a guinea-pig, after its surgical isolation from the testis, show a longer persistence of viability (or capacity to show movement on proper stimulation) when hormone is present. With a normal supply of hormone, persistence of viability is from sixty-five to seventy days, whereas it is approximately twenty-three days in the absence of hormone,⁴ Kabak in Moscow claims for his guinea-pigs that this is forty days without hormone. Viability is determined by hashing the isolated epididymus in physiologic solution of sodium chloride and observation of spermatozoon movements under the microscope.

Injections of active preparations of testis hormone have maintained the life of epididymal spermatozoa for periods approximately equivalent to those when hormone is secreted by an intact testis.⁵ It is presumed

that the action is a hormonal stimulation of epididymal cells to secrete some substance necessary for preservation of spermatozoa in a healthy state

(c) The electrical ejaculation test, specifically applied thus far to the guinea-pig, depends on inducing a seminal discharge on stimulation by 30 volts of alternating electric current applied to the head. The ejaculated semen, consisting of spermatozoa and secretions from the epididymis, prostate, seminal vesicle and Cowper's and probably other glands, becomes coagulated in a rubbery mass within a period of from two to three minutes after discharge. This reaction, described originally by Batelli,⁶ has been employed as a test for the hormone by Moore and Gallagher⁷ and by Kabak.⁸ Guinea-pigs castrated for a period of two months or more give either no ejaculate or only a clear watery noncoagulable discharge. Subcutaneous injection restores secretory activity in the seminal vesicle and prostate, and it is the interaction between secretions of these two structures that produces the coagulated mass normally constituting the vaginal copulation plug.

(d) The rat prostate cytology test, developed and applied by Moore, Price and Gallagher,⁹ depends on the fact that castration induces cytologic changes in the secretory cells of the prostate within a period of four days, longer periods after castration result in more pronounced involutionary changes, a maximum degeneration occurring in about twenty days. Injections of testis hormone begun immediately after castration prevent the appearance of castration changes or, if begun after their development, restore the normal secretory state of these cells.

(e) The rat seminal vesicle cytology test, developed and applied by Moore, Hughes and Gallagher,¹⁰ depends on cytologic changes in the secretory cells of this organ. The large cytoplasmic granules are lost within two days after castration, and within ten days the cells have regressed to approximately one-third their former height. Injections of testis hormone prevent castration changes from developing or restore the original condition.

Seminal vesicles of the mouse similarly respond rapidly to hormone loss and to injected hormone.¹¹ Changes in the acidity of seminal vesicle secretions have been found to occur after castration and that fact has been proposed as a test for the hormone.¹²

(f) Cowper's gland test in the rat may also serve as a hormone indicator. Heller¹³ has described the degenerative changes and the reactions of this gland to injected hormone.

(g) The vas deferens test is also adequate for indicating the presence of hormone. The reactions of this organ to castration and to hormone injections in the rat have been described by Vatna.¹⁴

All biologic tests are, of course, subject to the factor of animal variability, but the capon comb growth test

and the rat prostate and seminal vesicle cytology tests have proved fairly satisfactory as quantitative tests,¹ the capon test has been by far the most frequently used, and its application has been more nearly perfected. A complete substitution for the testis in the rat requires a daily injection of approximately two to three bird units of testis hormone to maintain the prostate and approximately four to five bird units for the seminal vesicles (Hansen).

SOURCES, METHODS OF EXTRACTION AND NATURE OF THE HORMONE

Pezard¹ was one of the earliest to obtain promising results from extraction of testes, saline extracts of cryptorchid testicles of swine injected into capons restored the comb almost to the proportions found in the cock. The testicles of the pig, ram, goat and bull have served as sources of hormone, as have also the urines of men and women, and the blood of the bull and the goat, comb-growth stimulating substances are also reported¹⁶ from male blossoms of a plant (*Salea caprea*).

The first successful extraction of the testis hormone was done by McGee,¹⁷ working in Koch's laboratory, from the lipid extractives of fresh bull testes. The method with its refinements and extensions by Gallagher and Koch is essentially as follows.

Fresh or frozen testicles from the bull, ground to a pulp, are extracted with four volumes of 95 per cent alcohol at room temperature. The active material is taken up from the concentrated alcoholic extract in benzene, which, when evaporated in vacuo, leaves a residue that is taken up in acetone and permitted to stand for some hours at -10°C . Evaporation of the acetone and suspension of the solids in olive oil gives a potent preparation suitable for animal injection. Further reduction of solids is effected by dissolving the acetone evaporated material in 70 per cent alcohol and agitation with hexane, by which procedure much inert material is removed. Evaporation of the alcoholic solution yields a heavy oily residue, which is dissolved in ether and shaken with aqueous 10 per cent sodium hydroxide, the majority of the activity remains in the ether layer. By repeating some of the treatments with 70 per cent alcohol, Gallagher and Koch have obtained a product of such potency that the bird unit represents a total weight of solids of approximately 0.01 mg.

Extractions of human urine have yielded a product possessing biologic effects similar to those of testis extractives (Loewe and Voss, Funk, Harrow and Lejwa, Dodds, Greenwood and Gallimore, Butenandt). Procedures of urine extraction have varied in the hands of different workers, but that described by Gallagher and Koch¹⁸ has yielded a product of relatively high purity. The urine is acidified with sulphuric acid to approximately 1 per cent by volume, filtered, and extracted with benzene in a continuous extractor. Benzene distillation yields a residue that is taken up in ethyl ether and extracted with 10 per cent aqueous sodium hydroxide, this treatment removes approximately 90 per cent of the solids, the ether layer containing the active substance is evaporated to dryness and is suitable for injections when dissolved in olive

oil Further refinement was carried on by fractional distillation under high vacuum, distillation at a temperature of up to 150 C removes approximately 50 per cent of the remaining solids Further purification by the use of ethylal, methanol and carbon tetrachloride as solvents and additional fractional distillation, produced a product of which a bird unit contained about 0.1 mg of solids

Crystalline material having a high activity has been obtained from urine extracts¹⁹ This involved, in the case of Butenandt, hydrolysis and fractionation with organic solvents of an active crude oil extracted from human urine Crystals were obtained by treatment with hydroxylamine of an aqueous-alcohol soluble fraction Butenandt estimates that approximately two million gallons of urine would contain something of the order of 1 Gm of the crystalline material Analysis of the crystalline material indicates a close similarity of the substance to theelin (keto-hydroxyestrin) The activity of the crystalline material was approximately one bird unit to each 0.001 mg, but the bird unit employed differs from that used by Gallagher and Koch It is a ketone-alcohol derivative with the suggested formula of $C_{27}H_{30}O_2$, its structural formula has been suggested (1932)

CONDITIONS GOVERNING SECRETION

It is unknown how early in life the testis begins to secrete its hormone Though the definite association of the embryonic development of the Wolffian duct with a testis is well known, it is not yet clear to what extent such early development is conditioned by the testis itself, or whether the hormone (if such exists in embryonic life) is the same as that produced by the mature testicle It is noteworthy that active substances can be extracted from the testis of the embryonic calf²⁰ but have not been found in the urine of young post-natal calves or in that of boys under the age of 10 years In the rat from thirty-five to forty days after birth, secretory differentiation of the seminal vesicle has occurred, and some secretion appears in the lumen

The testicles are capable of secreting hormone much earlier than they normally do, injections of gonadotropic substances (pregnancy urine or extracts, placental extracts, pituitary tissue or extracts, pregnant mare serum) may induce development of the secretory state of the accessory reproductive organs much earlier than is normal Precocious puberty in boys, though pathologic, demonstrates that testes can function earlier than usual Puberty involves elements other than mere secretion of testis hormone, for conditions must be developed that stimulate this organ to its secretory activity The pituitary and probably other glands assume activities previously latent, and a general maturing of the entire organism is undoubtedly involved in this important phase of life

Subsequent to the normal attainment of its hormone secreting activity the testicle in different species exhibits two extremes of hormone secretion, with intermediate types (1) continuous secretion throughout reproductive life and (2) secretion at intermittent periods lasting only a few weeks during each year, such groups can be designated as constant breeders and seasonal breeders To the first group belong man, some other pri-

mates, rabbit, guinea-pig and rat, and to the second group belong the large majority of all vertebrates including the majority of mammals

Constant Breeders—The conditions under which testis hormone is secreted is much better known for the rat than for man, but presumably a parallel exists In the rat, testis hormone is secreted continuously after its start has been made, as can be determined by microscopic examination of the prostate and seminal vesicles, castration induces changes in these organs within two or three days Hormone storage in the body therefore does not exist to an appreciable extent, and a continuous secretion is required for the existence of a functional group of accessory reproductive organs Continuous hormone secretion exists in the guinea-pig also, as shown by similar amounts of ejaculate obtained each week during an entire year²¹ In man, twenty-four hour samples of urine show an excretion of the hormone, but I am unaware of daily analyses for a sufficient period to determine the degree of fluctuation in renal output

Secretion of hormone varies in rate among different individuals of the same species if the gross size of accessory reproductive organs can be taken as a criterion This means presumably that existing concentration of hormone within the body varies, but it is not clear whether this means a greater secretion or lowered elimination of the substance through the kidneys, nothing is known regarding the variability of the renal threshold of excretion

The testes are not self regulating organs that control their own periods or rate of function It has been abundantly demonstrated by Smith and Engle,²² Zondek and Aschheim²³ and many later workers that the anterior lobe of the pituitary gland regulates the activity of the sex glands Removal of the pituitary is followed by cessation of germ cell production and hormone secretion Introduction of fresh pituitary material into hypophysectomized males restores testicular function Hormone secretion is thus controlled from without and not by the regulative activity within the testes

Hormone secretion by the testicle is modified by nutritional conditions Maintenance of rats on a diet deficient in vitamin B reduces, or abolishes, hormone secretion Restriction of the diet to inanition levels, but with excessive B-requirements, produces similar effects²⁴ In each case it is believed that the anterior pituitary is the real center of injury, since (a) the testicles of such vitamin B-free or inanition animals respond immediately to injections of hypophyseal extracts and secrete large amounts of hormone and (b) the hypophyses of vitamin B-free²⁴ and inanition animals²⁵ have a lowered capacity to stimulate the gonads of immature animals

Undescended testes of mammals, though failing to produce germ cells because of the lack of scrotal function,²⁶ continue to secrete hormone in apparently undiminished amounts This is apparent from observations on naturally occurring undescended testes of man and other mammals as well as in experimentally produced cryptorchid conditions Thus, a guinea-pig having one testicle removed and the second one confined in the abdomen a few days after birth will continue to produce

coagulable ejaculates for periods longer than a year, this occurs when the remaining testicular mass represents approximately 2 per cent of the normal. There is insufficient evidence to permit one to state whether the quantity of hormone secreted is greater or less than would occur with two normal testicles, or whether cryptorchid testes cease to produce hormone earlier than do normal testes.

Ligation of the vas deferens has been practiced on man with the presumption that closure of the outlet passages from the testis induces degeneration of the germinal epithelium and hypertrophy of the interstitial cells and thus greater secretion of hormone, which is supposed to have a rejuvenating effect. The facts are that closure of the outlet passages does not of itself lead to germinal epithelium destruction, that it is questionable whether hypertrophy of interstitial cells occurs, that there is no available evidence that more hormone is secreted or that testis hormone has a rejuvenating effect on the organism.

Seasonal Breeders—Sharply contrasted with continuous hormone secretion is the condition in which breeding and hormone secretion is restricted to a single short yearly period. This condition is characteristic of practically all vertebrates below mammals (excepting a few forms such as the fowl) and also of the greater number of mammals.

Conditions existing in the ground-squirrel (*Citellus tridecemlineatus*) have been subjected to a rather thorough study and the yearly events in this form may be used to represent the annual mammalian cycle.²⁷ *Citellus* breeds in April or May when accessory organs are at the height of their secretory function. By June (in the Chicago area) hormone secretion has diminished as shown by beginning involution of the reproductive system. The animal goes into hibernation about October or November, and testis hormone secretion is practically negligible until February. It emerges from hibernation usually in April. Thus, despite the continuous presence of testes, it secretes hormone during four months and at a submaximal rate during part of this period.

An experimental study of this interesting condition in the ground-squirrel reveals that the accessory reproductive organs respond at once to injected testis hormone, hence the involution of these organs is due to a diminished testicular secretion and not to refractiveness to hormone. Furthermore, administration of substances that stimulate testicular activity (fresh pituitary tissue, extracts of dried pituitary, or extracts of pregnancy urine) cause a sudden increase in size and functional activity of all accessory reproductive organs equal to that found at the height of the breeding period, this can be accomplished at any period of the year. It is apparent, therefore, that testes may be present but may not secrete hormone and that they can be stimulated to sudden activity by gonadotropic substances. Wells has determined that hypophyses taken from these males at the approach of, or during, reproductive activity contain a high potency for stimulating the gonads when implanted into immature female rats but that hypophyses removed during the period of sexual quiescence fail to exhibit this power. It is suggested, therefore, that seasonal periodicity in hormone secretion is controlled basically by the anterior pituitary.

CONTROL OF HORMONE SECRETION

The testicles are capable of secreting large amounts of hormone before the stage of puberty, but they do not, in adult life they secrete only a certain amount of hormone, though capable of much greater secretion, only 2 per cent of the normal fresh weight of testis tissue may secrete as much as two normal testes, two testes may be present for months and not secrete a detectable amount of hormone, all these facts present an interesting functional puzzle that invites speculation as to the controlling forces active in regulating sex gland function.

A suggested mechanism of reciprocal interactions between the gonads and pituitary has been developed on the basis of experimental work in this and other laboratories to account for conditions that exist in constant breeders as well as in seasonal breeders. Other papers present the ideas more fully and the evidence suggesting such an explanation.²⁸

It is well established that anterior pituitary secretions stimulate the gonads to function and that the presence of these secretions is necessary for maintenance of the function, variability in production or release of pituitary secretions induces variabilities in gonad function. It has also been abundantly demonstrated that the gonad hormone of either testis or ovary so influences the pituitary as to make lesser amounts of pituitary secretions available to the organism for inciting gonad activity.²⁹ In the case of constant breeding males, therefore, the pituitary appears to exercise a continuous secretion of the substances that stimulate gonad activity, though always far below its maximal capacity to secrete them, the inhibiting action of gonad hormones on the pituitary apparently affords a check on the production of its secretions this check being released when the gonads are removed. Many workers since Engle,³⁰ and Evans and Simpson³¹ have confirmed the observations that the pituitary from castrate animals of either sex is a more potent sex gland stimulator than that from normal animals of the same sex. That the normal testicle is capable of secreting greater amounts of hormone than it normally does is indicated by its response to the administration of gonadotropic substances. The effect of gonad hormone inhibition of the pituitary and the resultant failure of testis function is well illustrated by injecting estrogenic substance into normal males, both germ cell production and hormone secretion fail.³ The pituitary is rendered less potent by administration of gonad hormone this is demonstrated by implanting pituitaries from animals that have received large doses of the hormone.²⁹

In the strictly seasonal breeding types it is indicated that the pituitary does not secrete continuously and that in some manner certain environmental agencies play an important part in its activity. Manipulation of environmental agencies such as duration of daylight or changes of temperature have been revealed to have a pronounced effect on reproductive phenomena. Thus, Rowan³² in

Alberta increased the length of the daylight period by a few minutes each day with electric lights and caused the testes of a small bird (*Junco hyemalis*) to increase hundreds of times in weight and to mature spermatozoa during outside winter temperatures of 40 below zero C or F, progressive shortening of the daylight period led to progressive testis involution. Bissonnette³⁴ has confirmed this and by a similar technique induced a mammal (ferret) to mate at entirely unusual periods. Craig-Bennett³⁵ could control the reproductive state of fish to a remarkable degree by mere changes of temperature and could induce the breeding state at practically any period of the year.

It is thus strongly suggested that the controlling influence which regulates hormone secretion is a reciprocal interaction between the gonad and the pituitary gland. The oscillations between these, granted other conditions are normal, appear to regulate the intensity of action of each gland by the mutual interplay of their secretions, but in some animals an extraneous factor from the environment participates in the control of activity. Evidence has been obtained on the ferret that the effect of light is induced through the hypophysis. The environmental factor operating on the ground squirrel does not appear to be light.³⁷

ONE TESTIS HORMONE OR MORE?

The question whether the testis produces more than one hormone is not settled at the present time. If more than one substance is produced the facts available indicate a similarity so close that all are extracted by the same means and react alike to steps in purification. The same preparation of hormone extracted and purified by methods employed in Koch's laboratory will (a) induce the growth of the capon comb (b) prevent or repair all known castration changes in the accessory reproductive organs of the rat, (c) restimulate castrated guinea-pigs to produce typical coagulable ejaculates, (d) maintain the life of epididymal spermatozoa in the guinea-pig (e) prevent the development of castration cells in the pituitary and (f) restore the accessory reproductive organs in the ground-squirrel.

The chief evidence thus far presented for the secretion of at least a second hormone, believed to be derived from the activity of the germinal epithelium, comes from the work of Martins and Rocha³⁶ in which it is claimed that 1 Rats made cryptorchid experimentally maintain a normal set of accessory reproductive organs but show castration cells in the pituitary. 2 Hypophyses from experimental cryptorchid rats are more potent as gonadotropic agents than are those from normal animals. 3 Experimentally produced cryptorchid rats when joined in parabiosis with normal females induce a continuous estrous cycle in the normal female partner, normal parabiotic male partners do not have this effect. 4 Castrated rats implanted with fresh testis tissue, or injected saline extracts of these do not develop castration cells in the anterior pituitary but show an atrophied set of accessory reproductive organs.

In my estimation, further work is needed to establish as a fact that more than one hormone is secreted by the testicle. A sufficiently careful study should be made of the conditions under which the pituitary cells become castration cells. Furthermore the effects of quantita-

tive variations in both sex hormones and pituitary hormones must be subjected to rigorous examination. Until this phase of the problem receives more light, it is advisable to withhold judgment on the unity or duality of the testis hormone.

CLINICAL SIGNIFICANCE OF TESTIS HORMONE

The question of clinical application of testis hormone is a large one. Important considerations in regard to its application at present are, first, the availability of the product, second, the dosage, and, third, its usefulness as a drug.

The principal available sources of the hormone at present are testicles of large mammals and human urine. In the course of studies on extraction, purification and chemistry of the hormone carried on in Koch's laboratory several tons of bull testes have been utilized and hundreds of gallons of human urine have been extracted, yet one difficulty in advancement of knowledge of the hormone lies in obtaining sufficient quantities for experimental work.

Nothing is known regarding the usual needs of a normal man or the quantity necessary for daily injection into a castrated man to constitute a replacement dose. In a mature rat the daily dose sufficient to maintain the prostate gland and seminal vesicle in an approximately normal secretory state represents the material extracted from approximately 300 Gm of fresh bull testes or the extract from 500 cc of human urine. The quantity that would be required as a replacement dose in man may only be conjectured, since neither the relative sensitivity to the hormone nor the threshold of response of man is known. The amount excreted in twenty-four hour samples of urine has been determined for individuals, but the relation between the amount produced, or used effectively, and that excreted in the urine is undetermined.

From animal experimentation two points have been determined. 1 Hormone storage in the body does not exist and daily administration by injection must be given to maintain a normal secretory state of the accessory reproductive organs. The absence of a single day's injection of estrogenic substance is registered as a colored bar on regenerating feathers of a brown leghorn fowl.³⁷ 2 Some structures respond to a lower threshold of hormone than others, hence complete replacement requires the maintenance of a sufficiently high concentration to affect only those structures that respond to the higher concentrations. The prostate gland of the rat, for example is maintained in a structurally normal state by from one-third to one-half the amount of hormone required by the seminal vesicles.

The therapeutic value of the hormone cannot be stated at present. This question is pertinent. What is the function of this hormone in man? The logical approach to the answer is obviously the study of the castrated individual and biologically knowledge of the effect in man is very fragmentary. This is understandable, perhaps when one considers the popular conceptions under which both the layman and the clinician have grown up. What man has not been subjected to the popularly accepted opinion that loss of virility was indeed almost equivalent to death? Admitting that the physiologic effects of castration are extremely important, the real problem for consideration is the biologic aspect. Psy-

chologic states may as well be treated with substances more easily obtained than testis hormone

Prepuberal castration differs from postpuberal in both man and other animals. In man at puberty the indexes of maturity such as characteristic hair growth and distribution, attained growth of the genitalia, the deepened voice and physical stature have been established. They are not markedly changed, if at all, by postpuberal loss of hormone, but loss of the testes prior to puberty may cause modifications in these characteristics, modification of growth is not so clearly established. Eunuchs are said to be approximately one half tall and slender and one half short and fat, a cross section analysis of normal men is not greatly different. Despite the delay in epiphyseal union on long bones in castrates, it cannot yet be stated with exactness that castration greatly alters body proportions.

The fundamental biologic function of sex hormones is unquestionably the conditioning of the accessory reproductive organs to handle the sex products (germ cells) in a manner to insure their proper meeting, and the conditioning of the animal to respond characteristically and at the proper time in a manner to insure propagation of the race. Both functions, it must be admitted, are indispensable for reproduction. In the higher forms of life, however, it becomes apparent that the psychic responses depend on conditions not entirely under the influence of hormones. Thus prepuberally castrated guinea-pigs will exhibit for months strong pursuing tendencies toward females. Stone³⁸ determined that the white rat will copulate up to five or eight months after castration. It is known that apparently healthy males are often poor service animals, though definitely proved to be secreting normal amounts of hormone by the condition of their accessory reproductive organs. Mating instincts, or the copulatory desires, are extremely complicated and involve so many factors of mentality that it becomes questionable how important testis hormone is in inducing particular psychic states.

Against the concept that mating inclinations in man are lost after castration are the reports of promiscuity of eunuchs. This has been noted many times, and more recently McCartney³⁹ examined twenty-three eunuchs, finding ten cases of gonorrhea. The mental reaction and psychic state of the problem is well represented by the case of Rowe⁴⁰ of a man castrated at 25 years for pathologic reasons, who though previously energetic and widely traveled became an unambitious lethargic individual. The outcome of an interest in a young woman led to marriage nine years after his operation, with entire satisfaction on the part of both partners. His renewed outlook on life was followed by his rehabilitation and the successful pursuit of a new business venture. Psychotherapy in many cases may abolish the preconceived notions of the results of testicular damage, and the conception of the importance of the hormone in psychic conditions in man may have to be completely revised. The castrated man should receive a great deal more study.

Much has been made in medical literature of rejuvenation, increased length of life, mental improvements and the like in man by means supposed to involve changes in hormone production. For centuries man has castrated his domestic animals, even for improvement,

yet no one has shown that the life of them, or of castrated man, is shortened, indeed, the eunuch is reported to be a long-lived individual. Neither has castration been shown to be detrimental to an animal other than as concerns breeding powers. Whereas truth may lie in the statement that eunuchs are usually less progressive and energetic than normal men, their social status may play a larger part as a conditioning factor than does the loss of their testis hormone. History records high attainments for eunuchs in government, military and other walks of life. It is yet to be demonstrated that testis hormone in any way sharpens the mentality, prolongs life, aids digestion or sleep or imparts the host of other benefits it is alleged to bestow. Biochemical tests involving metabolism studies, urine analyses, blood chemistry, respiration and the like have so far failed to reveal any consistent development attributable to the absence of testis hormone.

As a final consideration it should be pointed out that from existing evidence testis hormone cannot be considered in any sense a stimulating agent for supposedly hypofunctioning testes, the hormone unquestionably stimulates the accessory reproductive organs but not the gonads themselves. Rather than acting as a stimulating agent on the gonad, injections of hormone in sufficient concentration are actually injurious to gonad tissue present. Injections of estrogenic substance into normal female rats,⁴¹ dogs⁴² and monkeys⁴³ do not stimulate the ovary but are positively injurious. Injection of estrogenic substance into normal males destroys germ cell production and hormone secretion. Testis hormone injected into young normal males suppresses growth of the testis and causes visible injury to the seminiferous tubules,⁴⁴ it probably lowers or abolishes hormone secretion, but this cannot be detected since the injection of the hormone more than counterbalances the loss of that produced by the organ itself. The injurious action of the hormones on gonad tissues is believed to be through the hypophysis, making unavailable to the sex gland the necessary substances from the pituitary for normal gonad activity.

In short, the gonad hormones are not gonadal stimulants, nor is the product of any specific endocrine gland a stimulating agent for that gland itself. If testis hormone proves to be of value in the clinic it will no doubt find one application in prepuberal castrates, as a measure adopted to produce evident signs of maturity to relieve the individual of the mental stigma of being markedly different from his fellows. For stimulating greater hormone production in an individual possessing some testis tissue, gonadotropic agents, and not testis hormone, will no doubt become the measure for application. This procedure appears already to have given results of clinical value in certain types of cases.⁴⁵

From this discussion it is no doubt apparent that the question of the clinical value of testis hormone is by no means settled. For attaining dependable results the problem must be considered from the broad point of view of social background and biologic principles. Real advancement must rest on honest critical work rather than on poorly conceived sporadic experimentation with hastily assumed results and unsubstantial claims.

SUMMARY

principal sources of testis hormone at present are articles of large mammals and human urine. Testis hormone is obtained from the lipid fraction and has been sufficiently purified to yield crystals having potency. It appears chemically to be a ketone-alcohol, the only method of detecting its presence consists in reactions produced in suitable animals. It is secreted continuously, or periodically, in different species, and secretion is largely under the control of the pituitary gland. It is uncertain whether more than one hormone is secreted by the testis. Its clinical use is questionable, its primary function is the control of the accessory reproductive organs, it is a testicular stimulant.

Therapeutics

THE THERAPY OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, M.D.
CHICAGO

—In their elaboration, these articles are submitted to members of the attending staff of the Cook County Hospital. The director of therapeutics, Dr. Bernard Fantus. The suggestions expressed by the various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed, the series will be published in book form.—Ed

THERAPY OF ECLAMPSIA

From a therapeutic point of view, eclampsia might be defined as a condition of metabolite intoxication accompanied by hyperpnea and a tendency to convulsions. As this syndrome occurs most especially in the late stage of pregnancy, the therapy of puerperal eclampsia is indicated here. With elimination of the items of obstetric therapy, this outline of treatment might be equally applicable to nonpuerperal eclampsia, whether it occurs in children, who, next to the puerpera, are most prone to convulsions, or in adults. For treatment of infantile "eclampsia" see Therapy of Spasmophilia. The functional pathology of eclampsia might possibly be visualized as a toxic angiospasm occurring as a reaction to certain poisons on the part of the system to obtain greater renal elimination by greater blood perfusion of the kidney. Unfortunately, when angiospasm extends to the brain blood vessels it is likely to cause cerebral edema, increased intracranial pressure and convulsions, and such angiospasm may in turn lead to constriction of renal blood vessels and diminution of urinary elimination. This vicious circle is fatal unless it is broken upon by correct therapeutic measures. Its treatment is much more successful than its treatment while eclampsia is more prone to result when the renal tissue is diseased, it may also occur without any renal or permanent renal tissue abnormality. The puerpera may, of course, have convulsions due to one of a great many different other causes as may the patient with nephritis. If all such convulsions were

called "eclampsia," the treatment to be discussed here would be erroneous for all the convulsions of other than the sketched pathogenesis. This is the reason why the term "eclampsia" should either be abandoned or else limited to a meaning that has practical value in treatment.

PROPHYLAXIS

The prophylaxis of eclampsia is an important part of prenatal care. It requires routine examination every two weeks during the last months, of blood pressure, urine and body weight, and for edema. Eradication of foci of infection, especially by dental care, should be insisted on.

Blood Pressure—A tendency to a rise in blood pressure (over 130 systolic, 70 diastolic), especially the diastolic, or excessive gain in weight (over 400 Gm per week) should at once be met by recording blood pressure readings twice daily and

1 A salt poor, low protein and low fat diet. An abundance of fruit and vegetables and carbohydrates, milk (at least three glasses a day), a small amount of protein and fat (one helping of meat and one egg daily), a minimum of salt and of spices, and from six to eight glasses of water daily should be taken.

2 Magnesium sulphate purgation, as required.

3 Skin hyperemia production, with its blood pressure reducing tendency. Profuse or exhausting diaphoresis is not intended. (a) A general electric light cradle for from fifteen to twenty minutes daily, or to the point of incipient perspiration, followed by a dry pack, or (b) a warm bath (100 F) daily for fifteen minutes, followed by a dry pack, or (c) general ultraviolet irradiation with a minimal erythema dose, the lamp at 75 cm distance, for from two to seven minutes according to the intensity of the rays or the sensitiveness of the patient, to different fourths of the body surface every other day, the various surfaces being irradiated again at each next round for possibly one minute longer until pigmentation or constitutional reaction sets the limit, which may be reached with fifteen minutes' exposure.

4 General regimen. The patient should avoid chilling and reduce her physical and mental activities.

Preeclamptic Stage—When the blood pressure does not recede promptly or if it exceeds 140 or when either albuminuria (more than a trace) or edema (especially facial) or both add themselves to the hypertension, the patient should be immediately hospitalized. Nonprotein nitrogen estimations, blood chloride determinations (if edema is present), and carbon dioxide combining power tests along with repeated retinoscopy will furnish an index as to progression or regression of the toxemia. Other measures include

1 Absolute rest in bed, which alone will often do wonders in the reduction of blood pressure and the relief of other symptoms. If the patient is restless, potassium bromide (4 Gm daily) and chloral hydrate (from 1 to 2 Gm daily) or phenobarbital (0.10 Gm, two or three times a day) will permit sleep and comfort.

2 Fasting. No feeding should be allowed and moderate drink restriction should be enforced for a day, followed by a salt-poor diet, e.g., oatmeal gruel and later by a lactovegetarian diet (1,500 calories daily). No tea or coffee should be taken. Edema indicates limitation in fluid intake (to 1,000 cc a day) until the edema is gone, then gradual increase in the fluid intake, provided the urine elimination increases proportionately.

Nephrology has too largely been dominated by tissue pathology. For the treatment of treatment syndromic classifications are needed that yield clear and unmistakable therapeutic indications.

3 Purgation by magnesium sulphate (30 Gm, best given in ice cold effervescent lemonade) every six hours until watery bowel movements are obtained, then 15 Gm daily the first thing in the morning

If the blood pressure goes down and no other symptoms appear, the patient is watched carefully, until term, for recurrence of symptoms. The patient should report at once if disturbance of vision, dizziness or unusual headache should appear

Threatened Eclampsia—If, in spite of these measures, the blood pressure, measured three times daily, continues to rise (systolic 150 mm, diastolic pressure 100 or higher) or if increasing toxemia is revealed by the study of the continuous twenty-four hour specimens of urine, the blood tests or other signs or symptoms, such as apathy or restlessness, or the appearance of headache (which need not be severe but is unaccounted for by other causes) or when visual disturbances or epigastric pain associate themselves, the uterus is promptly emptied, as these symptoms may mean the imminence of convulsions within a few hours or days, and as the maternal mortality of actual eclampsia is about 25 per cent and the infantile mortality almost 100 per cent

Interruption of pregnancy in the preecliptic stage, the single most important indication of which is the rise in blood pressure, not only saves the mother's life but also prevents subsequent invalidism from resulting permanent kidney impairment if the pregnancy is permitted to continue. Labor may be induced or cesarean section practiced. The method to be chosen for the induction of labor will depend on a number of facts, chiefly the proportion between the size of the fetus and the diameter of the birth canal

(a) If there is no disproportion and the symptoms are not urgent, 60 cc of Castor Oil given by mouth or through a stomach tube may suffice to induce labor within twenty-four to forty-eight hours. At this time the dose may be repeated, if the first dose failed, provided the symptoms show that there is no urgency

(b) Rupture of the amniotic sac almost invariably succeeds in initiating active labor within twelve to twenty-four hours

(c) Cesarean section should be done in rapidly advancing signs of threatened eclampsia, i. e., threatened eclampsia of an alarming nature, and in definite disproportion between the fetus and the birth canal

This treatment may seem radical, but it is actually conservative, for at least seven dangers threaten the toxic pregnant woman

- 1 Kidney and liver damage
- 2 Placental infarction, with death of the fetus
- 3 Premature separation of a normally implanted placenta
- 4 Temporary or permanent injury to the optic nerve
- 5 Bronchopneumonia from aspiration or inhalation anesthesia
- 6 Cerebral hemorrhage
- 7 Death from eclampsia convulsions and exhaustion

If these facts were crystallized in their minds, attending physicians would be more particular to start prevention early and to act more promptly in emptying the uterus than most physicians do at the present time

Labor should be conducted with all possible freedom from pain or trauma. Obstetric analgesia should be practiced during labor to avert the onset of convulsions by giving, for example, Morphine Sulphate (0.015 Gm) hypodermically, repeated in four hours if required, and Phenobarbital Sodium (0.10 Gm) by mouth, repeated in two hours and later every four hours, as required

If, during the second stage, labor becomes very slow or the blood pressure rises, indication for forceps or version is present

TREATMENT

When convulsions are present, an emergency exists that requires immediate and constant attention. If the convulsion occurs at home, morphine (even 0.03 Gm) should be given immediately by hypodermic injection to quiet the patient during transfer to the hospital. The indications may be classified as (1) sedation, (2) hypohydration, (3) support and (4) operation

1 Sedative treatment consists of the promptest possible administration of morphine hypodermically, chloral by rectum, and magnesium sulphate intravenously

Morphine Sulphate, 0.015 Gm by hypodermic injection, is to be repeated in one hour if required, provided the patient has not been given it before, then not oftener than every four or eight hours. Respirations should not be depressed to less than ten per minute. As soon as it can be made ready, one should also give a Chloral Hydrate enema giving 2 Gm of chloral for the first dose and a smaller quantity after two hours, and then at intervals of from four to eight hours as required

Chloral Enema

R	Chloral hydrate	8.00 Gm.
	Mucilage of acacia	30.00 cc
	Water to make	60.00 cc

M Label: Tablespoonful (15 cc.) in 150 cc of water given slowly by rectum. Give 10 cc dose after two hours if required. After this not oftener than every four to eight hours

Magnesium Sulphate is given slowly intravenously in doses of 20 cc of 10 per cent solution of the crystalline salt every hour until the convulsions are under control, and subsequently at longer intervals as indicated by blood pressure readings taken hourly. It is contra-indicated if there is coma or marked acidosis (carbon dioxide combining power less than 20 volumes per cent). Calcium chloride solution (5 per cent) should be kept in readiness for slow intravenous injection if alarming respiratory depression should occur, 25 cc may suffice to produce immediate improvement. If facilities for intravenous injection are not available, 10 cc of 25 per cent magnesium sulphate solution may be given intramuscularly

While all this is going on, noise and visitors are taboo. The greatest possible degree of quiet should be maintained, and the room should be relatively darkened. The patient must not be left alone even for a minute. During convulsions she should be restrained gently to prevent self injury. A towel, clothes pin or gag should be used to prevent biting the tongue. Lateral decubitus and elevation of the foot of the bed should be maintained to permit outward drainage of mucus and saliva and prevent their aspiration. Oxygen inhalation given immediately after each convulsion to relieve the cyanosis promptly is desirable. If mucus and saliva accumulate, these should be removed gently and frequently, best by means of suction apparatus

2 Hypohydration by phlebotomy of hypertonic dextrose solution is of importance, because in these cases there is a relative hypoglycemia (with liability to liver degeneration) as well as a tendency to cerebral edema. One may give 250 cc of 25 per cent dextrose solution (slowly, over a period of from thirty to forty-five minutes) and repeat this dose four times daily. It is also important to administer 250 cc of 25 per cent dextrose solution intravenously shortly (possibly fifteen min-

utes) before the birth of the child, to protect the infant against hypoglycemia which may be responsible for the high neonatal mortality.

Depletion may have to be practiced simultaneously, as all osmotherapy increases blood volume and tends to raise blood pressure and subtheal pressure secondarily. Hence guided by the blood pressure and provided the patient is not anemic, one may practice venesection which must be copious (500 cc) and performed rather rapidly to produce the result. If opportunity for venesection is not present, or if withdrawal of blood is considered undesirable, sequestration of blood in the limbs (for half an hour at a time) may be of some help.

Lumbar puncture should also be performed if conditions do not seem favorable and, if the cerebrospinal fluid pressure is high, escape of the fluid should be permitted. This must occur very slowly—literally drop by drop—for fear of herniation of the medulla through the great occipital foramen, which would result in sudden death.

It is obviously nonsensical while such treatment is practiced to "push fluid," as by saline hypodermoclysis. It must also of course be understood that most of this circulation depressing therapy is contraindicated in the presence of definite circulation insufficiency.

3 Supportive treatment may be required as by cautious and graded administration of fluid as soon as the object of the dehydration treatment has been accomplished. Phlebotomy of from 2 to 3 liters of 5 per cent dextrose in Physiologic Solution of Sodium Chloride until chloride appears in the urine and then of 10 per cent dextrose phlebotomy is likely to be beneficial. If sugar appears in the urine, insulin (see Diabetes) is indicated. A stimulant to the circulation may be needed, such as strophanthin (0.5 mg intravenously), which may be given in the dextrose phlebotomy.

4 Surgical obstetric intervention, if possible, should not be undertaken until the convulsions have been controlled, for emptying of the uterus does not stop the convulsions, though it usually prevents them. Accouchement force is not a part of the treatment of eclampsia. The uterus should be emptied without violence. Even low forceps application is done reluctantly and never with ether anesthesia because of danger of pneumonia. Antemortem cesarean section is rarely needed, because the child is usually dead at such a time.

Kidney decapsulation may possibly save the life of a patient with deep coma and anuria, when other measures seem to fail.

POSTPARTUM CARE

As in any severe case of preeclamptic toxemia convulsions may occur from twenty-four to forty-eight hours after delivery, sedative and other measures as described should be continued for several days. It is well to give as a routine, soon after labor, a hypodermic injection of Morphine Sulphate 0.015 Gm.

Blood pressure readings and the urinary output should be recorded daily.

The blood should be examined for nonprotein nitrogen retention.

The low protein and salt poor diet should be continued until edema has disappeared. Then fluid should be given freely, provided the kidney can respond to the appeal.

If the blood pressure and urine do not return to normal within two weeks after delivery, the therapy of nephritis (q.v.) is indicated.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS STIMULATED THE INVESTIGATION OF SHORT WAVE DIATHERMY AND THE THERAPEUTIC CLAIMS MADE FOR IT IN ORDER THAT THE MEDICAL PROFESSION MAY NOT BE MISLED INTO BELIEVING THAT THIS FORM OF THERAPY HAS UNUSUAL HEALING POWERS AND OTHER CLINICAL ADVANTAGES. THE COUNCIL FEELS THAT IN THIS AS IN ALL OTHER FORMS OF MACHINE THERAPY THE THERAPEUTIC CLAIMS MUST BE SUBSTANTIATED BEFORE THE MACHINES ARE ACCEPTED. IT FEELS THAT BY THIS STUDY AND BY SIMILAR STUDY OF OTHER NEW PHYSICAL THERAPY APPARATUS THE PROFESSION CAN BE MOST GREATLY BENEFITED. THE COUNCIL HAS THEREFORE AUTHORIZED PUBLICATION OF THE FOLLOWING ARTICLE.

HOWARD A. CARTER, Secretary

TISSUE HEATING BY SHORT WAVE DIATHERMY

SOME BIOLOGIC OBSERVATIONS

BERNARD MORTIMER, PH.D., M.D.

AND

STAFFORD L. OSBORNE, B.P.E.

CHICAGO

The introduction into physical therapy of apparatus generating high frequency electric and electromagnetic currents (now becoming generally known as short wave diathermy) has aroused a wide response and has stimulated much investigation. There is an increasing interest and literature on the use and effects of these currents but the multiplicity of therapeutic claims and the varieties of nomenclature have served rather to confuse the issue. The observations, if confirmed, may obviously have a wide range of interest and application in biology and medicine. Consequently it is especially necessary to approach the entire subject with a healthy skepticism in order to make an impartial critical evaluation.

The chief claims for short wave diathermy revolve about the following points:

- 1 Greater and more uniform penetration of heat into the body
- 2 Special selective thermal action
- 3 Specific biologic action
- 4 Specific bactericidal action

1 *Greater and More Uniform Penetration of Heat into the Body*—It is not entirely clear to us what is meant by "deeper thermal penetration" (as the advertisements read), since there is no adequate method of measuring this factor in the living body. The comparison of short wave radiation with roentgen radiation is, we believe entirely fallacious and misleading. The production of heat in any organ of the body in a short wave field is not a static affair, as will be brought out later. Likewise, there is no evidence to support the claim that the thermal gradient observed with conventional diathermy is reversed when short wave diathermy machines are substituted.

The experiments on which the claims of uniform and penetrating heating have been based are all phantom model or other in vitro experiments of the nature of the work of Pariseau.¹ This investigator, using agar-salt mixtures and a heat sensitive substance, tetraiodomercurate of silver (which is canary yellow when cold and orange red when hot) as an indicator, has attempted

Aided by a grant from the Council on Physical Therapy of the American Medical Association from the Department of Physiology and Pharmacology and the Department of Physical Therapy Northwestern University Medical School.

¹ Pariseau L. E. *Canad. M. A. J.* 20: 146 (Feb.) 1929.

to show the heat distribution by the color change. The interpretation of the results of this work is open to serious criticism. In the first place, the color of the indicator changes quickly when the temperature is raised above its critical point, in the second place, as Pariseau himself warns, a uniformly colored field does not mean a uniformly heated field. Furthermore, it is difficult to see how results obtained from experiments on beefsteak or on amputated limbs, which, devoid of circulation and nerve supply, are not even approximately representative of the actual physiologic conditions, can be validly applied to the living body. We do not believe it is possible to predict, from phantom model experiments, the response of the living body, with its variety of reactions and compensatory mechanisms, to this form of energy.

2. Special Selective Thermal Action.—From a mathematical and physical study of the heating of electrolytes in high frequency fields McLennan and Burton² and later Patzold³ and Reiter⁴ have shown that the heating depends on the specific conductivity of the liquid and rises to a maximum for a certain conductivity. This maximum is the more marked the higher the frequency. The conductivity at which the maximum effect occurs is shown to be proportional to the frequency. The distribution of the field in the interior of a heterogeneous body is determined largely by the dielectric constant and the heating by the conductivities. For a given wavelength there is a maximum heating effect produced in a medium, the specific conductivity and dielectric constant of which are connected with the frequency by the relation $2C = nK$, C being the specific conductivity in absolute units, K the dielectric constant, and n the frequency.

Extending this mathematical and physical relationship to the body, McLennan and Burton⁵ suggest that a selective heating effect is possible from a knowledge of the characteristic electrical constants of the substances of the body, and by suitable choice of wavelength the heating of a particular part of a heterogeneous body may be favored over that of neighboring regions.

However, there are at least two very serious and insurmountable limitations to this concept, one being the extent to which temperature per se operates on conductivity to increase this factor. Frequencies that might show selective heating at room temperature might be much less effective at body temperature and still less so as the tissue temperature rises as a result of the treatment, since the conductivity rises with temperature. Secondly, as one of us⁶ has shown, the blood flow and the rapid interchange of heat in the living body may render the differences of temperature negligible for all practical purposes, which McLennan and Burton themselves also point out.

Schliephake's⁷ work as well as that of others⁸ on selective thermal action and uniform and penetrating heating has been done mostly on dead tissue and tissue outside the living body, and as Schliephake himself says "It remains for further studies to determine the presence or absence of parallel selective reactions in

the living human, hence final conclusions from the facts can be drawn only after comparison with similar observations in living human material."

3. Specific Biologic Action.—Among the first to suggest specific biologic effects of currents of high frequency were Gosset and his co-workers,⁹ who reported that various types of plant tumors when subjected to massive exposures in a 2 meter field were killed, death being preceded by an acceleration in their rate of growth. Later Schereschewsky,¹⁰ working with a transplantable Rous sarcoma in mice, reported that he had shown a maximum lethal action between wavelengths of 3.75 and 15 meters. He stated that the tumors did not feel hot but that, on the other hand, the microscopic picture of them suggested coagulation necrosis. Recently, Pfomm¹¹ asserted that he reduced the toxicity of a rat sarcoma by the use of a 3.2 meter wave, the tumor receding in size until the thirty-eighth day, after which it began to grow again.

The earlier work has been reviewed before⁶ and need not be repeated, except to say that, aside from the report of Mellon, Szymanowski and Hicks, which needs confirmation, that they secured a definite attenuation of diphtheria toxin independent of the heat factor, there is not sufficient evidence to suggest an effect other than that of heat.

Schereschewsky¹² has lately reviewed his earlier work and has come to the conclusion that the sarcoma was killed by the heat generated in the tissue and that there was no evidence for specific lethal action of the radiation. Ross¹³ exposed twenty-two chickens inoculated with the Rous sarcoma to a 29 meter wave and reports that the duration of life was not prolonged and the growth of the tumor was not retarded. Haas and Lob¹⁴ used a 2.8 and 20 meter wave in the treatment of malignant tumors and observed no specific effects.

Other recent observations on the effect of exposure to high frequency currents include the work of Jellinek,¹⁵ who claims an increase over the controls in the weight of new-born mice that were exposed to a 3 meter wave four times daily for one hour at a time, and of Knudson and Schaible,¹⁶ who exposed white rats to currents of from 25 to 33.3 meters for from half an hour to one hour daily, raising the temperature to 40.5 C, and found no retardation of growth or change in the power to breed. These experimenters also¹⁷ exposed dogs to the same high frequency currents for from thirty to sixty minutes and found that the chemical changes in the blood were referable to the concentration resulting from the dehydration. The effect of high frequency currents on the oxygen consumption of frog muscle was studied by Fenn and Latchford,¹⁸ using 3.2 and 27 meters. They report no special effect that could not be attributed to the heating effect of

the current Nasset and his co-workers¹⁹ have made an extensive study of the physiologic effects of diathermy currents of 300 meters (diathermy) and 30 meters (short wave) on anesthetized dogs and report that at the higher temperature of from 42 to 44 C the protein metabolism judged from the urea production, may be doubled with no evidence of a disturbance to endogenous protein metabolism.

Fig 1—Heating of tissues of anesthetized dog (average of twelve). Current through thorax for ten minutes. Average rise in skin (average of twelve) machine I 14.14 degrees F, machine IV, 15.75 degrees. Average rise in lung (average of eleven) machine I 5.94 degrees machine IV 5.3 degrees.

Bierman and Fishberg²⁰ have recently reviewed the physiologic changes in the body during hyperpyrexia.

The tissues of guinea-pigs, dogs and rats, after exposure to a 25 meter radiation during which the maximum temperature rose to from 107.5 to 112.4 F, were examined pathologically by Jacobsen and Hosoi,²¹ and the changes found were the same as in fever produced by other methods.

4 *Specific Bactericidal Action*—Many studies have been carried out to determine whether the high frequency currents have any specific lethal effect on bacteria. Much literature has accumulated stemming largely from the writings of Schleichphake. With a co-worker, Haase, he reported²² a selective lethal action with specific wavelengths on various micro-organisms in vitro at 37 C. This work was extended by Liebesny and his co-workers,²³ who postulate that for every kind of bacteria there is a definite wavelength which has the most harmful effect and most quickly destroys the bacteria. He goes on further to say that the growth of

certain micro-organisms can even be promoted by certain wavelengths.

Confirmation of this work is lacking. On the other hand, much evidence is at hand in refutation. In this country Hicks and Szymanowski,²⁴ working with 25 meters on streptococci, staphylococci, B. diphtheriae, bacteriophage, and precipitating antibody for pneumococcus on the course of experimental infection in animals on specific desensitization, and on immunization by irradiated toxins, explain the effects on the basis of elevation of temperature produced. Izar and Famulari,²⁵ working with 4, 8 and 15 meters on B. typhosus, paratyphosus, dysentery Shiga, Ceylon A and B, and proteus X₀, report these micro-organisms unaffected by a twenty minute treatment. Groag and Tomberg,²⁶ in analyzing the results of Haase and Schleichphake that bacteria in culture are killed at 37 C by exposure to the short wave field, bring out the interesting explanation that because of "point heating" (similar to the phenomenon described by Escou in his oil and water emulsion in which steam escapes after exposure to the field even though the temperature of the emulsion is only 60-70 C) the bacteria may be brought above their thermal death point, which is essentially higher than the temperature of the surrounding medium. They remark that it is not necessary, as Haase and Schleichphake do, to invoke a new mechanism as a specific lethal action of short waves, which action in

Fig 2—Heating of tissues of anesthetized dog (average of twelve). Current through thorax for ten minutes. Average rise in skin (average of seven) machine V 3.1 degrees F diathermy 7.8 degrees. Average rise in lung (average of eight) machine V, 0.9 degree diathermy 6.54 degrees.

no wise was proved by their experiments. Groag and Tomberg repeated the work of Liebesny with the 4 meter and 15 meter wave on *Actinomyces bovis*, *Trichophyton tonsurans* and *B. coli*, and reached the

conclusion that the destruction of cultures by means of short waves is possible in every case so long as the electrical energy of the field suffices to generate the necessary point heat that brings the organisms above their thermal death point. Liebesny's other observations that bacterial growth may be promoted by short waves may also be explained by "point heating," which raises the temperature of the micro-organisms to their optimum temperature for growth.

Fig. 3—Heating of tissues of anesthetized dog (average of twelve). Current through thorax for ten minutes. Average rise in skin (average of eight) machine III 7.96 degrees F. machine II 3.4 degrees F. Average rise in lung (average of eight) machine III 1.81 degrees F. machine II 1.1 degrees F. Machine I no change in rectal temperature.

Hasche and Leung⁷ exposed cultures of staphylococci and streptococci in distilled water, saline solution bouillon and milk and on agar plates to short waves (from 8 to 16 meters) of different intensities for periods of time up to eight and one-half hours and observed no inhibitory or destructive effect on the bacteria.

Eidinow⁸ submitted suspensions of bacteria in serum to 3 and 4 meter waves eliminating the heating effect, and reports that he was unable to demonstrate any bactericidal action.

In our own laboratory we have subjected broth cultures of staphylococci, streptococci, *B. melitensis*, gono-

tulated. At present the results obtained can be fully explained, we believe, on the basis of the heat generated.

In view of the fact that many requests have been received for information regarding the therapeutic efficacy and physical characteristics of short wave diathermy apparatus, the Council was obliged to undertake investigations that would either confirm or refute the claims made in the advertising matter and descriptive literature. Although some of the firms having submitted machines to the Council did not hesitate to make questionable or misleading therapeutic and physical claims, they did fail to present conclusive evidence confirming these claims. Therefore because of the intense interest in this new field the Council deemed it advisable to go forward with certain investigations to substantiate if possible, the claims made.

The following machines were submitted for these tests:

- Machine I Two tube short wave diathermy (6 meter)
- Machine II One tube short wave diathermy (15 meter)
- Machine III Two tube short wave diathermy (24 meter)
- Machine IV Two tube short wave electromagnetic field (25 meter)
- Machine V Two tube short wave diathermy (16 meter)
- Machine VI Conventional diathermy for comparison.

EXPERIMENTAL

The experiments about to be described were designed to secure data on the heating effects of the various short wave diathermy machines submitted to secure data on the heating of various organs, and to observe the thermal gradient and any other changes which might occur.

Method of Recording Temperatures—Temperatures were taken by six thermocouples made of copper and constantan wires (28 gage Leeds-Northrup double

cocci, meningococci and *B. typhosus* to a 6 meter wave for twenty minutes during which time the temperature of the culture rose to 40 C without observing any change in the growth of the micro-organism. We have also subjected rats with experimental pneumonia for three minutes daily to the 6 meter wave without observing any change in the fatal course.

It becomes increasingly clear from a careful scrutiny and study of the literature that much scrupulously controlled experimentation must be performed before specific effects of high frequency currents can be pos-

cotton covered) soldered into the tip of a 16 gage lumbar puncture needle. The thermocouples were connected to the potentiometer (Leeds-Northrup portable precision type) through parallel double pole switches, a method that facilitated rapid reading of the individual couple.

The thermocouples were calibrated against a Bureau of Standards calibrated thermometer with scale division in one-tenth degree F.

Since the thermocouple itself is affected by the high frequency currents there were no thermocouples in place in the field during the passage of the current.

A Heating of the Tissues of the Dog (Anesthetized)—The determinations of the heating effects of

²⁷ Hasche E. and Leung H. *Strahlentherapie* 50:351 (June) 1934.

²⁸ Eidinow Albert. *Proc. Royal Soc. Med.* 28:307 (Jan) 1935.

short wave diathermy and conventional diathermy were made on dogs anesthetized with pentobarbital sodium, 30 mg per kilogram, reinforced by small additional doses whenever necessary. For the determination of the temperature changes in the viscera, the dog was laparotomized and a thermocouple inserted into the selected organ. With the liver and spleen the thermocouples were held in place by stitching to the peritoneum; for the kidney the thermocouple was inserted

Fig 4—Cannulas in right thigh. Medial cannula in quadriceps extensor and lateral cannula in subcutaneous tissue.

through the flank and held in place by stitching to the skin, after the kidney had been immobilized by stitching the capsule to the peritoneum, the thermocouple in the duodenum was fastened by securing it to the serosa. The abdomen was then

closed surgically. For the temperature changes in the skin in the muscle of the thorax and in the lung, the thermocouple was inserted into the same place before and after the passage of the current. At the conclusion of the day's tests the animal was killed and examined to verify the position of the thermocouples and to observe any gross changes in the tissue. The slight disturbance in each organ occasioned by the insertion of the thermocouple does not, we believe, alter the physiologic conditions enough to give misleading results, as the thermocouples responded instantaneously to any temperature changes.

The pad electrodes were applied to each side of the thorax and were separated from the skin by a 15 mm thickness of felt. (This thickness was decided on after many trials.) The dogs were subjected for ten minutes to the maximum output obtainable from each machine. In clinical practice, as will be brought out later, it is not always possible or desirable to utilize the maximum output, as the patient cannot tolerate it. For this comparative study, however, bearing in mind the limitations of the application, the maximum field was used for the following reasons. With several of the machines submitted for these tests, less than the maximum output produced no observable temperature or other changes. Thus by using the maximum output a very troublesome variable factor, the tolerance dosage, was eliminated and it became possible to observe the response of living tissue to this form of energy. With diathermy, metal electrodes of the same area as the pad electrodes, separated from the skin by a 15 mm thickness of cellulocotton soaked in 10 per cent solution of sodium chloride, were used. For the application of the electromagnetic field the cable was wound with four turns round the thorax.

The six machines were used in rotation on each dog, sufficient time being allowed between tests to permit the animal to cool (sometimes in the icebox) and return to thermal equilibrium. In this way, strictly comparable results were obtained on the same animal. Likewise by rotation no machine enjoyed any undue advantage of position, if such existed.

The results of these experiments are shown in the accompanying table and figures 1, 2 and 3. Twelve complete experiments were performed and several partial ones in which not all the machines were used

With the current applied across the thorax it was found that at the end of the irradiation the temperature of the skin and muscles of the thorax had risen considerably, the temperature in the lungs was somewhat less than that of the muscles. There existed a definite thermal gradient from the skin inward. At the same time the liver, kidney, spleen and duodenum heated to a lesser degree but each organ named underwent almost the same elevation in temperature, even though the last three organs were never in the short wave field and only part of the liver was. It is interesting to note that the body temperature, as indicated by rectal temperature, rose as the other organs lost heat. This illustrates the remarkable efficiency of the rapid heat interchange in the body, and the distribution of heat by the blood and other circulating fluids.

From our experiments with the short wave diathermy on anesthetized dogs we were unable to observe any greater penetration of heat or more uniform heating than with the conventional diathermy.

Attempts were made with several animals to obtain temperatures within the bones of the foreleg, but the trauma incident to drilling into the bone so disturbed the circulation as to produce a temporary stasis, which vitiated the results.

It should be pointed out again that in these experiments the complete output of the machines was used. Clinically, this is seldom possible owing to the limitation of skin tolerance but in these experiments it was

Fig 5—Roentgenographic appearance of cannulas in thigh.

necessary for comparative purposes. Thus a machine with a high output is not necessarily desirable, since it might not be possible to use all the available energy for any local treatment in which the dosage is always necessarily regulated and limited by skin tolerance.

The importance of skin tolerance in the application of these high frequency currents cannot be over-emphasized. This is strikingly brought out in the experiments on the human subjects.

B Heating of the Tissues of Man—Experiments were similarly conducted on the thigh of human beings

Under aseptic precautions a nonmagnetic, nonconducting sheath (through which the thermocouple needle could be guided for temperature readings) was inserted subcutaneously and into the quadriceps extensor (figs 4 and 5). Temperatures of the skin, of the subcutaneous tissue, of the muscle and of the mouth were taken before and after a twenty minute clinical application.

Since the success of the utilization of this new form of energy depends to some degree on the proper technique

Fig 6—Heating of human thigh (eight subjects). Current on for twenty minutes. Average rise in skin machine I 7.9 degrees F machine IV 6.26 degrees diathermy 6.7 degrees. Average rise in mouth machine I 0.3 degree machine IV 0.7 degree diathermy 0.35 degree.

of application, a representative of each manufacturer was present at one or more of these tests for advice and guidance. With the pads, varying thicknesses of felt and bath toweling were used. For the application of the electromagnetic field, four turns of the cable were used, the thigh being covered with two thicknesses of bath towel. The surface next to the skin of the metal electrode of the diathermy was coated with a thin layer of K-Y jelly to insure better contact.

The six machines were used in rotation on the thigh, sufficient time being allowed between for return to thermal equilibrium. In these experiments the dosage was regulated entirely by the tolerance of the patient. With several of the machines and with diathermy, the maximum output could not be utilized for this local treatment.

The results of these tests on eight human subjects (male) are shown in figures 6 and 7. It is seen that there is a greater rise in the temperature of the subcutaneous tissue than in the underlying muscle, that the temperature of the skin rises markedly, and that the body strives to dissipate and distribute the heat as rapidly as possible, as shown by the rise in the mouth temperature and rapid drop in the skin temperature. There appears to be a thermal gradient in the tissues of the thigh following short wave diathermy. There does not appear to be any selective thermal action or any evidence of more uniform heating. The short

wave machines, except one, do not appear to have any advantage over diathermy in the heating of body tissues, actually most of them are inferior.

In connection with machine IV, it appears from figure 6 that the skin does not become as hot as the subcutaneous tissue, but this is due, we believe, to two factors: 1. The coil cannot be as closely applied to the thigh as the pads and hence the skin has the opportunity to lose heat by radiation. 2. Owing to the greater rise in the temperature of all the tissues in the field and to the rise in body temperature, sweating occurs on the thigh and as a result there is a further cooling effect from the evaporation of the sweat. In this connection the question must be raised as to whether it is physiologically or therapeutically desirable to subject tissue to such marked temperature changes in such a short space of time, although this could be controlled by using less than the maximum output of this machine.

During the course of this investigation cuff electrodes, which did not come with the original model submitted, were sent in for trial by one manufacturer. With the cuff electrodes applied to the thigh, the following temperature increases were obtained (average of three tests): subcutaneous, 5.4 degrees F, muscle, 4.8 degrees, skin, 5.4 degrees, mouth, 0.53 degree.

The full clinical discussion of the therapeutic indications, applications and limitations of these new high frequency currents will follow in another article.

SUMMARY AND CONCLUSIONS

Experiments have been performed on twelve anesthetized dogs and on the thigh of eight human subjects to study and measure the heating effects of short wave diathermy and to observe any other changes that might occur. Five short wave machines were used, a 6 meter, 15 meter, 16 meter, 24 meter, 25 meter and the conventional spark-gap diathermy.

1. There is no conclusive evidence from the literature nor were we able to substantiate the claim of specific biologic action of high frequency currents (short wave diathermy). In our opinion the burden of proof still lies on those who claim any biologic action of these currents other than heat production.

Fig 7—Heating of human thigh (eight subjects). Current on for twenty minutes. Average rise in skin machine II 5.7 degrees F machine III, 6.3 degrees machine V, 6.2 degrees. Average rise in mouth machine II 0.01 degree machine III 0.07 degree machine V 0.07 degree.

2. The experimental work that claims specific bactericidal action for these high frequency currents may be more rationally explained, we believe, on the basis of "point heating," which raises the temperature of the micro-organisms above their thermal death point without a corresponding elevation in the temperature of the medium. It still remains to be demonstrated whether such test tube results can be secured with infection in the body.

3 Our own work on the machines submitted shows that there is a thermal gradient from the hot skin to the less hot tissues within

4 There is no evidence from reliable experimental work on living subjects that short wave diathermy possesses a more uniform penetration of heat into the body than the conventional diathermy

5 The possibility of special selective thermal action is a very remote one

6 We do not believe that it is possible to predict the response of the body to high frequency currents from phantom model or other in vitro experiments

BONNIE BRAND GOLDEN SYRUP

Manufacturer—The Pioneer Maple Products Company, St Paul

Description—A table syrup, corn syrup with refiners' syrup, flavored with vanilla extract

Manufacture—Corn syrup and refiners' syrups as received from the manufacturers, are mixed, heated to 88 C, tested for proper consistency and allowed to stand thirty minutes after which time the vanilla is added. The syrup is automatically filled into friction top cans and sealed

Analysis (submitted by manufacturer) —	per cent

(No methods are available for accurately determining the composition of syrups of this nature, therefore the foregoing analysis is roughly approximate.)

Calories—3 per gram 85 per ounce

Claims of Manufacturer—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding and as a syrup for cooking baking and the table.

FRIGID ZONE CRAB

Distributor—Alaska Salmon Company, San Francisco

Packer—Alaskan Glacier Sea Food Company, Petersburg, Alaska and Seattle, Wash

Description—Canned cooked meat of Alaska crabs

Manufacture—The crabs are caught in open salt water fishing beds in Alaska 15 miles from the nearest settlement. On receipt at the cannery the crabs are inspected and only those alive are used which are held in bins until inactive are butchered the backs are removed and the crabs are eviscerated, thoroughly washed and boiled for fourteen to twenty minutes. The meat is removed from the shells washed with dilute acetic acid solution and then with water dipped into concentrated salt solution and packed by hand in enameled cans lined with parchment paper. The cans are sealed under vacuum and processed ninety minutes at 110 C. The canned meat averages 60 per cent leg meat and 40 per cent body meat. Eight hours

elapse between catching and canning. Operators handling the meat wear canvas gloves

WARRANTY SIEVED PEAS

Manufacturer—The Nielsen Corporation, Ltd, Oakland Calif

Description—Sieved peas prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt

Manufacture—Fresh peas as received from the field are shelled thoroughly washed, and subsequently processed and canned by essentially the same procedure as described for Warranty Sieved Spinach (THE JOURNAL, Feb 2, 1935, p 399)

Analysis (submitted by manufacturer) —

	per cent

Carbohydrates other than crude fiber (by difference)	9.8

Calories—0.6 per gram 17 per ounce

Vitamins—The method of preparation and processing insures the retention in high degree of the natural vitamin values

Claims of Manufacturer—Specially intended for infants, children and convalescents, and for special smooth diets. Only warming is required for serving

CELLU JUICE-PAK BLUEBERRIES

PACKED IN UNDILUTED JUICE WITHOUT ADDED SUGAR

Distributor—The Chicago Dietetic Supply House, Inc., Chicago

Packer—Loggie & Company, Island Pond, Vt

Description—Processed blueberries packed in undiluted juice without added sugar

Manufacture—Ripe blueberries are cleaned with a fanning machine, conveyed to the factory, inspected by a government inspector for presence of worms, thoroughly cleaned of leaves and dirt by machine and hand, washed cooked, filled into cans and automatically sealed. Before shipment, the cans are inspected and labeled

Analysis (submitted by distributor) —

Calories—0.5 per gram 14 per ounce

Claims of Distributor—Packed in undiluted blueberry juice without added sugar

OMAR WONDER FLOUR

Manufacturer—Omaha Flour Mills Company, Omaha

Description—Patent flour milled from washed hard winter wheat, bleached

Manufacture—Selected hard winter wheat is cleaned washed tempered, scoured and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate (0.33 ounce per barrel) and nitrogen trichloride (3.6 Gm per barrel)

THE PROBLEM OF MYELOMA

William McIntyre,¹ an English physician, published in 1850 the report of a case of "mollities and fragilitas ossium." His description of the onset with vague neuritic pains, the occurrence of spontaneous fractures of two ribs, and of the later evolution and course of the disease combine to give a typical clinical picture of a multiple myeloma. In addition, he made an interesting observation of the peculiar "altered condition of the urine." At his request Bence-Jones² made a study of the patient's urine and confirmed his observations. Addition of nitric acid cleared the urine, but a yellowish coagulum formed about one and one-half hours later, which, however, redissolved on application of heat and precipitated out again on cooling. The effect of boiling was to redissolve the coagulum. The postmortem examination with a particular study of the involved ribs was made by Dalrymple.³ McIntyre called attention to the essentially malignant character of the condition, though he felt that it did not act in all respects as a true neoplasm.

In 1873 von Rustizky,⁴ working in von Recklinghausen's pathologic institute in Strasbourg, reported a careful postmortem study of a case of multiple tumors of the bones of the trunk. According to him, similar cases were mentioned by Virchow, who, however, considered them cases of myelogenous sarcoma. To von Rustizky belongs the credit of proposing the name myeloma for the condition. To complicate further the questions of terminology and priority, Bozzolo⁵ in his work referred to the careful description of the clinical symptoms of the disease by Kahler⁶ and proposed that it be called Kahler's disease. Recent contributors used the hardly justifiable term Kahler-Bozzolo disease alternately with that of multiple myeloma.

The clinical characters of myeloma are those of an insidious onset with vague neuritic pains, progressive anemina, multiple involvement by tumor of the skeletal trunk, pathologic fractures, most characteristically of a rib, backache with signs of involvement of the spinal cord, and the presence of Bence-Jones bodies in the urine. The prognosis is hopeless, the patients dying on an average two years after recognition of the condition. Classification of the tumor on a histologic basis appears not to have any value in the case of myeloma. The designation erythroblastoma, lymphoblastoma or plasmocytoma, because of the preponderance respectively of immature red cells, lymphocytes or plasma cells, carries little significance. The essential histologic feature of the tumor is that it is made up of all the immature elements of the bone marrow. Abrikosov⁷ described the occurrence in myelomatous lesions of crystals, which appear either as needles or as rhombic prisms. They lie embedded in fibrous tissue and display at the periphery giant cells, an appearance indicative of absorption. Abrikosov believed that these crystals formed as the result of action of the chondroitin-sulphuric acid developed from destroyed tissue. Because similar crystals could be obtained from the Bence-Jones bodies, he asserted that myeloma is not a primary disease of the bone marrow but a variable structural reaction to an altered intermediary metabolism. The original concept of myeloma as a true neoplasm was replaced by that of a systemic disease of the hematopoietic system related to aleukemias and leukemias. However, the dictum that myeloma is always multiple was in turn contradicted by the recent reports of purely localized myelomas, the clinical features of which bear some resemblance to the localized form of osteitis fibrosa. The solitary myelomas appear to be almost exclusively plasmocytomas. They display a tendency to involve the long bones of the extremities as well as those of the trunk. They appear to be benign and do not give rise to metastases. Rutishauser⁸ and Geschickter⁹ each reported a case of myeloma of the femur. Mathias¹⁰ reported a case of solitary myeloma of the skull cured by surgical removal of the tumor. Roentgenologic study of his case eighteen months later failed to reveal a recurrence or metastases. There was no anemia, and Bence-Jones bodies were not found in the urine. Walthard's¹¹ case on postmortem study proved to be a circumscribed plasmocytoma of the third thoracic vertebra. It appears, therefore, that besides the generalized form of myeloma with its hopeless outlook there is a localized form amenable to surgical therapy and offering a favorable prognosis.

STAPHYLOCOCCUS TOXOID

The demonstration of the production of highly potent toxins by various strains of staphylococci and the observation that the human blood stream contains measurable amounts of the antitoxin have materially changed the conception of staphylococcal infections. As a direct result of these determinations the possibility of treating chronic staphylococcal infections by means of formaldehyde-treated toxin (toxoid) has arisen. Both favorable and unfavorable results of the clinical use of staphylococcus toxoid have been experienced. On the basis of the available evidence one brand of this product was recently accepted by the Council on Pharmacy and Chemistry.¹ Two new clinical reports have lately appeared in the *Lancet*.² In one of these (Murray) the results are especially susceptible of analysis. Murray treated 116 cases of chronic staphylococcal infection. The patients were from 6 weeks to 82 years of age. In ninety patients whose stories seemed reliable the average duration of the disease had been six and one-half years and the longest appeared to be fifty-four years.

The presence and measurability of circulating staphylococcus antitoxin in the blood permits certain objective observations in addition to the clinical course. Thus Murray found that the quantitative difference in circulating antibody between his group of patients before treatment (exclusive of those with osteomyelitis) and 100 normal controls was not apparently significant with the possible exception of a low titer of antibody in the group having carbuncles. It was further possible to observe the change in circulating antibody resulting from the treatment with toxoid. All the patients in the series had the same first course of injection of toxoid (0.05, 0.1, 0.2 and 0.4 cc. of a product of unstated potency at weekly intervals) the author unfortunately records dosage in fractions of a cubic centimeter rather than in dermonecrotizing units of the toxin from which the toxoid was prepared. The blood was retested one week after the fourth dose. At this time the average amount of staphylococcus antitoxin was approximately eight times the average level found before the beginning of treatment except in cases of osteomyelitis.

The injection of staphylococcus toxoid produces local swelling and pain but the number of really severe local reactions has been remarkably small. In order to tabulate the clinical results, Murray divided his cases into acne, blepharitis, furunculosis, carbuncles and the like. Patients were classed as 'recovered' if fresh lesions ceased to appear during the course of injections and did not reappear during the six to eight months of subsequent observation. Of the 116 patients fifty-one recovered, fifty-six were improved and nine received slight or no benefit. The best results were apparently

obtained in furunculosis and the least satisfactory in acne. A comparison of the clinical results with the changes in antitoxin titer under treatment indicates that the increase in titer appears to have some prognostic value. It is impossible to predict from the initial titer, however, whether or not the final result will be favorable.

In another paper Dolman reports the results of treating with toxoid 306 patients suffering from chronic staphylococcal infections. Less susceptible of analysis than Murray's paper encouraging results are reported.

"The acquisition of clinical immunity," he says, "could be correlated with an increased staphylococcus antitoxin titer of the serum." In general, a return of infection occurred only after there had been a considerable fall in the titer of circulating antitoxin. The high antitoxin titer and renewed clinical improvement could usually be restored by further treatment with toxoid.

The administration of staphylococcus toxoid to patients with chronic staphylococcal infections usually produces a rise in the titer of circulating antitoxin. This rise fails to occur by treatment with vaccines—the only other specific method. In the hands of these investigators the rise is associated with a measurable improvement in the chronic localized staphylococcal infection. Failures have been reported³ but these as Dolman⁴ has pointed out, occurred chiefly in cases of acne. In addition, the questions of the specificity of the strains of staphylococcus employed in making the toxoid, and the potency of the preparations used must be considered. To date the best results have been recorded with recurrent boils and the least successful with acne. The procedure described seems at least, to warrant careful study with a view to more precise determination of its indications and limitations.

COPPER IN HUMAN HEMATOPOIESIS

Recent experimental investigations demonstrating the importance of copper as an essential hematopoietic agent in various laboratory animals have led to speculation regarding the role of this element in human blood formation. Many attempts have been made to elucidate this question, usually by studies of the therapeutic activity of copper in diseases involving the blood-forming mechanism or of the actual copper content of human tissues and excretions in health and in disease.

The data obtained in the majority of reports in the literature indicate that copper is without appreciable effect as a therapeutic agent in human anemias. Negative results have been reported on patients with pernicious anemia and with various types of "secondary" anemia. In the nutritional anemia of infancy, how-

ever, some recent evidence¹ seems to show that about one patient in twenty may suffer from copper deficiency and therefore may benefit from copper therapy. Experiments of this type on human patients are carried out with difficulty and further carefully controlled studies employing sufficient numbers of cases must be made before conclusions are drawn.

Direct chemical analyses of various human tissues and excreta have likewise failed to give definite information as to the function of copper in man. Copper is apparently present in significant amounts in many human tissues² and its presence in normal human blood has been demonstrated repeatedly. These observations, while suggestive, offer no direct evidence of the importance of copper in man. Analyses of the blood of patients with anemia, however, have yielded more significant information. The observation has been made³ and recently confirmed and extended⁴ that the copper content of the blood of anemic subjects is above normal. In the latter investigation the average copper content of the blood in a series of fifty healthy adult men and women averaged approximately 132 micrograms per hundred cubic centimeters. The blood of patients with various diseases, however, showed increases well above the normal. In no instance was there a value less than normal.

The diseases that were studied included pernicious anemia, Banti's disease, acute myelogenous leukemia, chronic lymphatic leukemia, malaria, gastric hemorrhage, arsenic poisoning, nephritis, carcinoma, tuberculosis and polycythemia vera. High blood copper was observed also in pregnant women. In the cases of pernicious anemia studied there appeared a relationship between the degree of "hypercupremia," the severity of the anemia, and the amount of iron present in the blood. The relation was inverse, the high blood copper being associated with a low blood iron and in general, a more severe anemia. The correlation between variations in these constituents was particularly striking in a single case of polycythemia vera treated with phenylhydrazine. The copper content of the blood was normal and the iron content was high before treatment was inaugurated. Simultaneous with the drop in erythrocytes following phenylhydrazine therapy there occurred a decrease in the iron and an increase in the copper of the blood. When treatment was suspended, these values returned to the original levels. The significance of these data is largely a matter of conjecture. The high copper content of the blood in anemic subjects may represent a compensatory response of the organism resulting in a mobilization of this hematopoietic catalyst, thus promoting a restoration of the normal cell

and pigment concentration in the blood, or the increase in copper may be a manifestation of an accumulation of this element in the blood as a result of its poor utilization or altered metabolism, a situation somewhat analogous to the hyperglycemia of diabetes mellitus resulting from an impairment of carbohydrate metabolism.

Although the foregoing investigations strengthen the opinion that a deficiency of copper does not exist in adult human subjects and that copper therapy is not indicated in human anemias, except perhaps in occasional cases of nutritional anemia in infants, some support is added to the thesis that a small amount of copper is involved in blood formation in man.

Current Comment

HORMONES IN THE TREATMENT OF HEMOPHILIA

The limitation of hemophilic manifestations to the male has provided a speculative basis for the theory that some substance peculiar to the female, possibly a hormone, inhibits the appearance of symptoms in girls and women. Some support for this hypothesis was obtained from experiments in which estrogenic substance could not be detected in the urine of hemophilic males whereas small amounts were consistently found in urine from normal males. It seemed possible, therefore, that the estrogenic hormone itself might be involved in producing the immunity of the female sex to this malady, and that the administration of the substance might produce a similar resistance in males afflicted with the disease. Experimental studies of this hypothesis have yielded conflicting results with regard both to the therapeutic efficacy of the estrogenic hormone and to the absence of this substance from the urine of the hemophilic. In a recent study,¹ data on two cases of hemophilia have been reported which clearly show that the administration of the estrogenic substances theelin and theelol was without effect on the rate of coagulation of the blood and that the amounts of estrogenic material excreted in the urine were no less than those found in normal subjects. Further data confirming the latter observation were obtained in another group comprising forty-five patients with hemophilia. Indeed, the average amount present in the urine of the patients was somewhat greater than that of a group of twenty-six normal subjects. Data were also presented in this report which demonstrated that the luteal hormone and an anterior pituitary gonadotropic substance were likewise without effect in the treatment of hemophilia. In view of the impure nature of the preparations of these two hormones now in use, however, it might be well to reserve final judgment regarding their effects until the therapeutic activity of the chemically pure, crystalline hormones themselves has been determined.

Medical Economics

TUBERCULOSIS AND INSURANCE

Tuberculosis, like diphtheria, after attacks by medical science and service for many years has been constantly declining. It is claimed by many workers in this field that universal and thorough application of existing knowledge would practically eliminate these diseases in modern nations just as such an application has already almost rid these nations of plague and yellow fever that once were as great a threat to human life and health.¹

Reduction of mortality in tuberculosis depends largely on early and accurate diagnosis followed by prompt and proper treatment. Such a situation, at first sight seems to offer an excellent opportunity to test the comparative efficiency of medical service. Unfortunately there are many other factors that influence the incidence of tuberculosis and the rate of decline in mortality. Economic conditions, diet, pure milk, housing, overcrowding, occupation, age and race are some of the factors² that may be favorable or detrimental influences on both morbidity and mortality.

It is possible that when entire nations are included in comparisons of tuberculosis mortality there may be a tendency for some disturbing factors to cancel out and thereby lose some of their importance. This tendency is too uncertain to be

TABLE 1—Death Rates for All Forms of Tuberculosis Per Hundred Thousand in Great Britain*

accepted without warning. Such factors have much less importance when the rate of decline in mortality in two or more nations is compared. There was seldom any such change in these factors within a single country as would greatly influence this rate of decline. The important new factor in all the countries considered is the advance in the science and application of medical service, and this is exactly the factor that it is desired to measure.

The incidence of tuberculosis varies so closely with income that it has often been called a 'poverty disease'. The higher prevalence among low-paid workers and urban residents makes tuberculosis mortality an especially good test for the comparison of medical service under insurance with such service in private practice. The principal avowed justification of insurance is that it provides a medical service for the low-wage classes superior to that which they can provide for themselves from private medical practice. If insurance medical practice fails to do this, it forfeits its reason for existence so far as medical care is concerned.

It should also be noted that no country has ever been able to meet the problem of tuberculosis care and treatment through insurance alone. In both Germany and England with which

¹ Louis I. Dublin (Health Outlook for 1935 Inspires Optimism the Diplomat 7:32 [Jan.] 1935) says: "I believe that tuberculosis will continue to behave according to formula that is, with every succeeding year we shall observe a reduction in the death rate. We are nearing the end of the fight against tuberculosis. It is destined in a few years to rank among the minor causes of death—and the greatest reduction in mortality has taken place in the wage-earning population where the situation has always been the gravest."

² Transactions of the Nineteenth Annual Conference of the National Association for the Prevention of Tuberculosis July 1933. This meeting was devoted almost entirely to consideration of environmental factors in relation to tuberculosis.

it is proposed to compare conditions in the United States, there are elaborate and expensive organizations for the purpose of fighting tuberculosis similar to those found in this country. This renders conditions more closely comparable, since the dominant differing feature is the method of organizing and furnishing medical service.

Early and accurate diagnosis is of primary importance in the successful treatment of tuberculosis. It has been constantly urged by advocates of insurance that in private practice the economic obstacle is the principal hindrance to prompt and

TABLE 2—Tuberculosis Death Rate Per Hundred Thousand in Registration Area*

* Statistical Abstract of the United States 1934 p. 80

universal service and that insurance, by removing this obstacle, makes such service available to all the insured.

The one factor peculiar to the United States is the presence of a large Negro population with a high tuberculosis mortality rate.

The mortality rate for all forms of tuberculosis for Great Britain since 1921 is given in table 1.

In twelve years there was a decline of forty-two deaths per hundred thousand, an average annual reduction of 35 deaths per hundred thousand and a total decline of 37 per cent.

The corresponding figures for the registration area of the United States are given in table 2.

Public Health Reports³ gives the rate per hundred thousand for all forms of tuberculosis in twenty-eight states with 95,000,000 population as 56.5 for 1933. Taking the period 1920 to 1932 covered in the table there is a decline of 51.2 deaths per hundred thousand or 44.9 per cent in twelve years, an average annual reduction of 4.3 deaths per hundred thousand.

It has not been possible to locate figures for all of Germany comparable to those for England and the United States. The Epidemiological Report of the Health Section of the Secretariat of the League of Nations for September-October 1932 and January and February 1934 gives information from which table 3 was compiled.

Without attempting any mathematical comparisons of the figures in this table which might lead to the assumption of an accuracy that does not exist, it is evident that from no point of view do these figures indicate that insurance furnishes

TABLE 3—Death Rates Per Hundred Thousand for All Forms of Tuberculosis in Various Large Cities

Cities	1929	1930	1931	1932	1933
Chicago	77	65.9	66.2	57.4	56.4
New York	75	73.1	69.4	62.9	
*51 German cities	91	81.3	80.8	76.6	65.6
Berlin	101	91.4	91.4	85.8	87.3

a medical service that is more effective in the struggle against tuberculosis than is furnished in the United States under private medical practice.

This conclusion is strongly fortified when the mortality rates are given for the various states. It then becomes apparent how great has been the influence of the large Negro population in certain localities and how far in advance of any insurance countries are a number of important states with populations comparable as to industrialization and other features with England or Germany. Such comparisons cannot be pushed too

³ Mortality in Certain States During 1933 with Comparative Data for Recent Years Pub. Health Rep. 49:559 (May 4) 1934.

far, since it must always be remembered that higher incomes in this country create more favorable conditions for ameliorating or overcoming the ravages of tuberculosis. It is well to note also that taking considerable sums from these incomes to furnish the sort of medical service that is given under insurance might remove some of this advantage now enjoyed by American workers. Keeping these considerations in mind, the mortality rates by states are worthy of study.

Table 4 covers twenty-eight states, within the registration area, with a population of 95,000,000. The figures are based on a complete review and retabulation of the individual death certificates from each state.

In Germany and England nearly all employees in the wage classes most susceptible to tuberculosis are freely furnished with medical service through insurance. The advocates of insurance charge that in the United States these classes are denied proper medical care by reason of their economic condition. It is especially charged that this economic obstacle prevents early diagnosis of incipient diseases such as tuberculosis. These arguments raise two closely related questions. Is the reason for the failure to obtain medical service wholly, or mainly,

* Mortality in Certain States During 1932 with Comparative Data for Recent Years. Pub. Health Rep. 48:478 (May 5) 1933.

economic? Does insurance bring about an early diagnosis of tuberculosis?

Those who deal with tuberculosis in England are constantly complaining of delay in the detection of the disease. Some quotations from an official report are worthy of note.

During 1933 66,351 new cases were added to the notification registers of England and Wales as compared with 68,792 in 1932. This decline is more or less proportional to that in the mortality of the disease. It would however be more satisfactory if the decline became less rapid or ceased as this would imply that more patients were being notified at an earlier stage when the prospects of recovery were greater. It is unsatisfactory that out of the 61,789 new cases of tuberculosis notified to the Medical Officers of Health of England 3,072 or 5 per cent came to notice only after death viz 2,455 from the local registrars' returns of death and 617 from posthumous notifications. There is reason to believe that this figure is an understatement of the facts since it is known that some Medical Officers of Health still do not obtain returns of deaths from the local registrar.

Notification in the late stage of the disease is commented upon by many Medical Officers of Health in their annual reports. The Medical Officer of Health of Plymouth states that 50 per cent of patients died from tuberculosis within a year of notification.

There are some antituberculosis workers in England who maintain that insurance is to some extent directly responsible

for delay in diagnosis and proper treatment. One such physician⁵ imagines an insured sufferer from tuberculosis saying

had as it was before the Act was passed for a patient in a similar condition to myself to die slowly during four or five years, I am not now going to run the risk of telling my symptoms to and being examined by a medical attendant because he considering that I am suffering from pulmonary tuberculosis will bring it about through the operation of the Insurance Act that a worse fate shall overtake me. I shall be subjected to application of sanatorium treatment at a stage far earlier than could be detected before 1912 though I am a danger if careless with my sputum to my young children. I must carry on with my work as long as I can living at home because the Act does not offer me an option to live apart from my children providing the accommodation, except temporarily in a sanatorium.

It is not at all unlikely that the unfortunate administrators of the Act from those in the Ministry of Health to the tuberculosis officers and the panel doctors realize that they have to cope with a Frankenstein monster created when the National Health Insurance Act came into force in 1912. They probably are as well aware as anyone of the unimproved and even worsened outlook under the Act in most parts of England of those who are suffering from pulmonary tuberculosis but as administrators they are, with some notable and fortunate exceptions saddled with restrictions in a few parts only of the country has the crying need for the amelioration of the hardships inflicted on cases of pulmonary tuberculosis been met by the establishment of pulmonary hospitals or institutes where a considerable number of cases hitherto condemned to undergo sanatorium treatment are now being admitted for more effective and modern treatment.

A German physician⁶ recognizes a similar situation and says

it is a regrettable fact that pulmonary tuberculosis is seldom promptly recognized in general insurance practice. This is all the more significant since at the present time the outcome of treatment of pulmonary tuberculosis stands and falls with the period of the diagnosis.

The answer to the two questions would seem to be that the principal obstacle to the receipt of medical service at an early stage is not economic but personal and therefore is not removed by insurance.

In this and the preceding articles an attempt has been made to assemble the testimony offered by morbidity and mortality rates as to the comparative efficiency of medical service under insurance and in private practice. These statistics have been assembled to cover the following conditions:

- 1 Complete morbidity and mortality statistics for entire populations
- 2 Morbidity statistics for employees subdivided as to
 - (a) Number of illnesses per person per year
 - (b) Average duration of illness per person employed.
 - (c) Average duration of disabling illness among those who have such illnesses
- 3 Morbidity and mortality rates for diphtheria
- 4 Morbidity and mortality rates for tuberculosis

Judged by all these tests such information as is available agrees in support of the conclusion that the service received by the low-income classes is more efficient under private practice in the United States than under insurance in England and Germany, the two most extensive systems of sickness insurance now in existence.

NEW YORK CHANGES COMPENSATION CODE

The long struggle waged by the Medical Society of the State of New York to get rid of some of the abuses in medical care under workmen's compensation has taken a long step forward with the adoption of the O'Brien Kantowski medical abuses bill by the state legislature.

At the time the bill was signed Dr. Arthur J. Bedell, president of the state medical society, thanked the governor on behalf of the medical profession of the state and commented as follows:

'This law gives local county medical societies the opportunity to recommend qualified physicians for the various phases of compensation practice. These local groups of doctors will immediately take action to set up machinery to make the law effective.

For twenty years the old law has encouraged a system of selecting these doctors so that factors other than the character and fitness of the individual physician have been the deciding

⁵ Shaw, H. B. G. P. s and T. B. An Indictment—The Answer Brit. J. Tuberc. 28:60 (April) 1934.

⁶ Ahrensman, H. The Prompt Recognition of Tuberculosis in Kassenpraxis Medizinische Welt 8:982 (July) 1934.

⁴ Annual Report of the Chief Medical Officer of the Ministry of Health 1933 p. 124.

elements in determining the man to be employed. For years the medical profession has tried to obtain legislation to remedy a vicious system which has resulted in conditions little short of disgraceful. The new law will go a great way to cure these evils.

A new feature of the law will be that five physicians, named by the governor on the recommendation of the state society, are to represent the profession on the labor council, which has the ultimate responsibility for administering the law. This group of doctors will have supervision of all medical phases of the act.

The medical profession of the state accepts the serious responsibility of naming the doctors who are to practice compensation insurance with confidence that a marked improvement will be seen in the care which patients receive.

ANNUAL CONGRESS ON MEDICAL EDUCATION, HOSPITALS AND LICENSURE

Thirty First Annual Meeting held in Chicago Feb. 18 and 19 1935

(Continued from page 1422)

DR. ROY B. HARRISON, New Orleans, in the Chair

FEBRUARY 19—MORNING

JOINT SESSION OF THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS AND THE FEDERATION OF STATE MEDICAL BOARDS

SHOULD THE RADIOLOGIST THE PATHOLOGIST AND THE ANESTHETIST BE LICENSED TO PRACTICE MEDICINE?

Legal Aspects

DR. WILLIAM C. WOODWARD, Chicago. The question is not as I see it, as to whether roentgenologists and others of the classes named shall be licensed but whether the practice of those particular arts shall be limited to licensed physicians.

If roentgenology or pathology or anesthetization is applied for purposes other than of diagnosis and treatment, I do not believe that under any of the medical practice acts or under the general principles that govern the practice of medicine, it can be said that those arts are a part of the practice of medicine. When they are applied for diagnosis and treatment in my judgment, they are parts of the practice of medicine. That however does not require that they shall be performed solely by licensed practitioners of medicine. There are many functions of a physician that are being entrusted to unlicensed persons. The matter at issue, then, is not only the question as to whether roentgenology, anesthetization and pathology are parts of the practice of medicine but also whether a physician licensed to practice medicine can delegate to an unlicensed person his right to function in any of those fields. As a general rule, a physician may delegate to another the duty of performing some function that calls for no particular professional judgment. It may be the application of a bandage, the instillation of a few drops into the eye to produce local anesthesia or the administration of a hypodermic. They are purely what are termed administrative matters. But when it comes to the delegation of judgment that is not a lawful delegation. So in these cases the question comes as to whether roentgenology pathology and anesthetization as practiced by these unlicensed agents can be practiced without the exercise of substantial medical judgment. If it cannot, then an unlicensed agent is violating the law regulating the practice of medicine. If he does not have to exercise any judgment, the delegation is probably a lawful one. A surgeon practicing in some remote place, meeting with a sudden emergency, may have to submit his patient to anesthetization at the hands of the most ignorant kind of a person. If he doesn't call on that person to aid the patient will die, the operation cannot be performed. Therefore the circumstances under which a physician undertakes to delegate his

right to practice roentgenology or pathology or to administer anesthesia depends not only on the question as to whether the agent to whom authority is delegated has to exercise a professional judgment so to speak, but whether the circumstances of the case call for a delegation that would not otherwise be permissible. Some roentgenologists have attempted to draw an analogy between surgery and the practice of roentgenology, pointing out that the roentgenologist penetrates the tissues, as they say by means of the x-rays. The argument is not sound beyond a certain point. It is not sound because a person can consent to have his tissues penetrated by a knife or a needle by an unlicensed person, and that person will not be engaged in the practice of medicine unless the penetration is for the purpose of diagnosis, prevention or treatment. Of course, if the penetration involved calls for any grave risk of life, his own consent would be void and the person who operated would be liable to a criminal and a civil charge of assault, otherwise the performance would be entirely lawful. So long as the penetration of the tissues by x-rays is not for the purpose of diagnosis and treatment and as the penetration is done with the consent of the patient or some one lawfully authorized to consent on his part, I can't see that there is any necessity for limiting the performance to licensed practitioners of medicine.

I desire only to lay down a few general principles. It has been said that because a roentgenologist examines his patient to determine whether he can properly take a roentgenogram the performance is the practice of medicine and must be undertaken by a licensed physician. With that I am inclined to agree. If one sends a patient to a roentgenologist and asks him to determine whether a roentgenogram should or should not be taken or what treatment to administer, the dosage and everything of that kind clearly, I believe, the roentgenologist is practicing medicine, but otherwise it can hardly be said that he is. If one sends the patient to a roentgenologist asking that a roentgenogram be taken and the print be returned without any expression of opinion on the part of the roentgenologist, it is difficult to see where there is any professional judgment called for except on the part of the physician.

Another feature that must be considered is that if the law is going to limit the practice of roentgenology to licensed physicians roentgenologists will probably find themselves in the position of being compelled to employ nothing but licensed physicians as their assistants. Another point is as to whether it is possible to demonstrate any definite harm that is being done in the practice of roentgenology by unlicensed persons over and above the harm that is done in the practice of roentgenology by licensed persons who are incompetent. It is not merely a question of regulating the practice of roentgenology as between licensed persons and unlicensed persons, but, after all what the public wants in the regulation of roentgenology so that incompetents will be excluded. In the matter of pathology, the principles that I have laid down are very similar. It isn't enough to provide that there shall be an adequate plant equipment and personnel, but some provision must be made whereby inspectors will check up on the work of the laboratories. That I think is the only safe rule.

With respect to anesthesia the situation is somewhat different one that comes more nearly to bringing the practitioners into the practice of medicine, and yet I have failed to find a decision of a court, I have failed to find a statute that forbids an unlicensed person from practicing anesthetization if the person is administering anesthesia under the direction of a licensed physician. In other words, custom has grown up to such an extent that the administration of general anesthetics by unlicensed persons is definitely tolerated. In Arizona it is provided that a registered nurse may administer anesthetics under the direction of and in the presence of a licensed physician provided the nurse has taken a prescribed course of anesthesia at a hospital in good standing or is a graduate in the science of anesthesia from some recognized school or college. In Ohio it is provided that "nothing in this chapter shall be construed to apply to or prohibit in any way the administration of an anesthetic by a registered nurse under the direction of and in the immediate presence of a licensed physician provided such nurse has taken a prescribed course in anesthesia

at a hospital in good standing" In Washington it is provided that "nothing in this section shall prevent a registered nurse or trained office assistant from administering an anesthetic under the direct supervision of a licensed dentist" In West Virginia it is provided that "in any case where it is lawful for a duly licensed physician and surgeon practicing medicine and surgery under the laws of this state to administer anesthetics, such anesthetics may lawfully be given and administered by any nurse who has been duly registered as such under the laws of this state, provided such anesthetic is administered in the presence and under the supervision of a licensed physician and surgeon" In Kentucky it is provided that any person living in this state or who may hereafter come into this state who administers anesthetics except on the prescription of a legally qualified physician or in any way performs the duties usually performed by physicians without having complied with the provisions of law or opens an office for such purpose, shall be subject to the penalties " This is a group of states in which the legislatures have definitely authorized the administration of anesthetics by other persons than licensed physicians The courts have taken a somewhat similar view

Bearing in mind what I have said, I hope that those who are going to discuss it will consider their subjects from the standpoint not only of practitioners but also of the public and from the standpoint of the unlicensed person who will be excluded from business under any rules that may limit practice to licensed physicians and that they will consider their subjects from the standpoint of hospital work It is important in asking for corrective legislation to proceed at once to collect evidence that will show not merely that the use of roentgen rays, the use of anesthetics and the practice of pathology by persons who are not licensed in the practice of medicine is bad but that it is worse than the practice of those several arts by physicians who are inadequately trained to practice them Unless one is prepared to present the facts and figures he will not get anywhere with a well informed legislative committee

The Radiologist

DR. B. R. KIRKLIN, Rochester, Minn. There can be but one answer to this question and that answer is in the affirmative Moreover, I hold to the opinion that, so far as may be feasible, the practice of radiology should be entrusted only to radiologists who are, or soon will be, diplomates of the American Board of Radiology Nevertheless disagreements arise as to how and by whom radiology should be practiced Considerations of finance underlie most of them, but in the deep background are certain pernicious inheritances from customs of the past When the x-rays were discovered, potential applications of the new agent to medicine were obvious but most physicians felt that personal employment of the rays was beneath professional dignity Consequently for a long time the making of "x-ray pictures" was delegated chiefly to photographers and amateur electricians A diagnosis was reached by comparing the general appearance of the "picture" with other "pictures" accepted as representative of normal or abnormal conditions and the judgment of the lay radiographer was likely to be considered Thus was founded the notion that radiology is essentially a layman's art, and the belief has not yet been eradicated completely Because technicians are usually employed and extensive apparatus is necessary, radiology is commonly rated as a laboratory specialty but laboratories proper deal with specimens whereas radiology deals directly with patients and really belongs to clinical medicine as a medical specialty The persistent impression that radiology is necessarily a laboratory branch of medicine fosters the notion that the technical element is dominant

During the formative period of radiology when it had not yet found itself there naturally was a scarcity of well qualified radiologists Within recent years however, when it was realized that this branch of medicine had the scope and importance of a specialty, many physicians adopted it as their field but their qualifications varied widely Instead of a scarcity, there now seemed to be a surplus, but neither the public nor the medical profession had any means of judging their qualifications To bring order out of chaos the national radiologic

organizations, acting jointly and with the approval of the American Medical Association, have established the American Board of Radiology, the purpose of which is to elevate radiologic standards by determining the competence of those who profess to be radiologic specialists Although the board began to function scarcely more than a year ago, it has already certified to the competence of approximately 400 radiologists The number will be greatly increased when the examinations are completed

For several years, many of the hospitals have employed radiologists at a fixed salary, or a salary plus a percentage of the receipts from the department, or such percentage only Of late some of these hospitals have treated the radiologist unfairly by depriving him of a just wage and appropriating substantial profits from the department, thus using it as an important source of income Dissatisfaction on all sides has become so acute that the entire problem of proper relations between hospitals and radiologists has been brought up for settlement A plan has been put into effect at Cleveland by which the fiscal affairs of the technical service are separated from those of the professional service The hospital fixes all charges for the technical work attends to their collection and pays all expenses of this service The technical service is supervised by the staff radiologist and he receives compensation from the hospital for that supervision, but as a consultant he is placed on the same footing as other members of the staff, assesses all fees for his service as consultant, and collects them himself Roentgenographic examinations are made at the order of the radiologist or of the physician in charge of the patient, but only the radiologist or his assistant is permitted to make roentgenoscopic examinations Interpretations are made by the radiologist when requested by the attending physicians, but the latter has the privilege of making diagnoses without consulting the radiologist

At first thought the Cleveland plan appears to be plausible, and the sincerity of its sponsors is obvious Nevertheless it seems to me that the new system not only fails to correct present abuses, but fosters a reversion to those of the past which were worse The principle that the radiologist, not the hospital, should fix and collect his fees is commendable But the Cleveland plan separates his just dues into two classes namely, wages that he earns as supervisor of the technical service, which are collected and paid to him by the hospital, and fees that he earns as a radiologic consultant which he himself collects Yet both his wages and his fees are professional earnings, for supervision of the technical service requires professional knowledge and, as supervisor, he is still the hospital's employee so that his independence is restored only in respect to his fees for consultation Moreover, in providing for supervision by the radiologist of the technical work, admission is made that the professional and technical services cannot really be separated This feature of the plan undoubtedly springs from the notion that the radiologist is primarily an artisan, secondarily and by courtesy a physician But if the radiologist is double, the surgeon also has a dual personality that of a skilled workman and that of a physician, and by the same logic he should be able to function in either capacity independently of the other If the new system were applied to him, the hospital would collect his wages as a workman but require him to collect his fees for professional service Just how the separation could be made staggers the imagination

The gravest objection to the new plan arises from the fact that although the staff radiologist is available for consultation the patient's attending physician, whether qualified or not, is permitted to make diagnoses from roentgenograms if he so chooses Certainly under this condition there will be an irresistible tendency to request fewer and fewer opinions from the radiologist with a corresponding reversion to the inefficiency of former days In explanation and justification of the privilege granted to the attending physician it has been argued that it is necessary to distinguish between minor and major radiology just as this distinction is made in surgery whereby any physician may perform minor operations but only qualified surgeons may perform major operations Minor radiology does not exist If radiologic examination is indicated at all, its results are always of major significance

I consider the Cleveland plan in its present form to be a definite step backward. It seems to me that the following plan would be practicable, equitable and efficient:

1 Place the department under the unimpeded control and financial management of the staff radiologist.

2 Require that neither examination nor treatment shall be carried out except by or at the order of the staff radiologist or of some other radiologic specialist selected by the patient or his physician and approved by the hospital or of a specialist deemed by the staff radiologist as competent to make examinations in a particular field. Of late the word monopoly has been used in this connection but it is not clear whether it is complained that the staff radiologist is given a monopoly as against other radiologists or that radiologic specialists are given a monopoly as against all other physicians. If the former is meant the proviso that any radiologist or any specialist who is qualified to make radiologic diagnoses in his restricted field may use the equipment of the department will dispose of the objection. If it is meant that radiologic specialists as a group are given a monopoly of radiologic work the answer is that precisely such monopoly is in the best interests of the patient, the general medical profession and the hospital.

3 Insist that after each examination a diagnosis shall be made and recorded by the radiologist or other specialist officiating. Hold the staff radiologist directly or indirectly responsible for every radiologic diagnosis made in the hospital.

4 Separate the finances of the department from those of the hospital but make the account books accessible to the hospital bookkeeper for inspection and audit. Let the department not the hospital collect all bills for radiologic service.

5 Out of the departmental revenues pay current expenses give to the hospital a reasonable return on its investment making due allowance for depreciation and freely acknowledge the right of the radiologist to whatever surplus remains.

The substitute suggested is not altogether novel and doubtless is susceptible of improvement. No plan can long survive unless it is fair to all concerned completely restores the radiologist to his rightful status as a physician and assures the maintenance of a high standard of radiologic service to the patient. Indeed, if the welfare of the patient is given first consideration, a proper solution of the problem will not be exceedingly difficult to find.

The Pathologist

DR. J. P. SIMMONS, Chicago. For the purposes of this discussion, pathologists may be separated into two main groups: (1) those who are engaged only in teaching and research in this field in large universities and (2) those who are concerned with the more practical aspects of pathology as applied to the diagnosis of disease, namely, clinical pathologists and the tissue pathologists who serve hospitals or commercial laboratories. The activities of the first or professorial group will have little or no direct effect on the diagnosis of disease or the treatment of patients and it would not seem necessary to require them to possess a license to practice medicine, although they should have an M.D. degree. The second group are concerned with the diagnosis of disease, the results of their work influence the treatment of patients, and, in my opinion, they should have a license to practice medicine.

Two aspects of the subject of this symposium should be differentiated in this discussion: (1) the advisability of requiring by law the licensing of all physicians engaged in the practical application of the principles of pathology to the diagnosis of disease, i.e., all clinical pathologists and those tissue pathologists associated with hospitals; and (2) the advantages to the pathologist himself of the possession of a license to practice medicine. The first aspect of the question might be decided on the basis of a relatively simple principle without the enactment of any new laws. In those states in which the medical practice act specifically makes the diagnosis of disease an essential part of the practice of medicine the practicing pathologist should be required to have a license to practice medicine just as the practitioner of any other specialty for he is practicing medicine under the meaning of the act. It would seem to be unnecessary to urge the passage of new laws to regulate the

practice of pathology. Existing laws and the common sense of the pathologist should be sufficient to meet the legal requirements pertaining to this specialty.

It is to the second phase of the question, namely, the advantage to the pathologist himself of a license to practice medicine that I would direct attention. It is because the pathologist is concerned with the diagnosis of disease and is, or should be, a consultant that he should possess a license to practice medicine before engaging in his specialty. The mere possession of a license will not make him a better pathologist. But with such a license he is on a legal equality with the clinician. The average clinician is inclined to deny the right of a pathologist to his proper position of consultant. The clinician who sees the patient seems to think that the pathologist, who often is not permitted to see the patient, knows little or nothing about disease. As a matter of fact the competent pathologist knows much more about disease than does the clinician. It is his comprehensive knowledge of disease that would make the pathologist a most valuable consultant if given the opportunity. The clinician may also feel that the pathologist knows nothing of the treatment of disease or the care of patients. True the pathologist is not primarily concerned with treatment. But rational treatment is possible only when the underlying pathologic condition is understood, and the pathologist is especially equipped to aid in obtaining this information. In many cases, perhaps the most important reason for denying the pathologist his rightful place as a consultant is the principle of reciprocity that is inherent in consultations. The pathologist not being engaged in clinical practice, is not in a position to reciprocate in the temporary exchange of patients. For these reasons the pathologist, whether he has a license to practice medicine or not, is relegated to the laboratory, is often treated in a patronizing manner by clinicians often his inferiors in the fundamental knowledge of disease, and is denied his proper place as a consultant to the detriment of the highest type of practice of scientific medicine.

Pathology is just as much a medical specialty as is internal medicine, surgery or urology, with as high ideals as any of them. Acquiring proficiency in this branch of medical science is as exacting and as time consuming as in any other specialty. Both the clinical pathologist and the tissue pathologist must of necessity delegate much of the mechanical part of his work to adequately trained and thoroughly supervised technicians. The clinician seems to forget that he too delegates much of his work to others. The clinical history is usually written by an intern. The physical examination is made by an intern or a resident. The practicing physician is aware that the work of these subordinates is of value only as it is done under his supervision and is confirmed, corrected and interpreted by himself. It is even more true that laboratory work done by technicians with little or no medical training is of value in diagnosis only when it is done under the immediate supervision of a trained pathologist. There are few things that are more conducive to careless methods of medical practice than the indiscriminate employment of technicians by clinicians who are capable neither of judging the qualifications of technicians nor of adequately supervising their work.

The pathologist is an indispensable factor in the practice of modern medicine. The clinical pathologist is concerned with the chemical changes in body fluids and excretions, the tissue pathologist with structural changes in the tissues and organs of the body including the blood. Both are especially concerned with the fundamental changes that underlie symptoms, physical signs and other manifestations of disease. The pathologist actually has a keener sense and a more comprehensive knowledge of the significance of symptoms and physical signs than does the clinician. He is especially prepared to interpret symptomatic physical signs and results of laboratory tests in terms of pathologic structural changes.

Years ago a committee of the American Medical Association drew up regulations with which clinical laboratories must comply in order to receive recognition by the Association. One of the most important of these regulations requires that to be recognized as a specialist a pathologist must be a graduate in medicine, must have satisfactory training in pathology, chemistry and other allied subjects for at least three years.

subsequent to graduation who is in good standing and has been duly licensed to practice medicine." These regulations doubtless work a hardship on small hospitals. I venture to offer a suggestion for the amelioration of this hardship. The first requisite will be the admission of pathologists to their rightful position as consultants in their specialty. Unless assured that proper recognition will be given them, capable young graduates will not go into this specialty.

Most towns of 5000 population have a hospital to which all the physicians in the community and neighboring smaller towns are permitted to bring patients and treat them. Such institutions need a capable pathologist even more, perhaps, than larger hospitals of higher grade. In spite of numerous important services which a pathologist could render, the superintendents of such small hospitals feel that they cannot afford a pathologist and the members of the staff must depend on the unsupervised activities of technicians for all laboratory work and are never able to check their clinical diagnoses by postmortem examinations performed by a competent pathologist. Such a deplorable state of affairs could be remedied by suitable recognition of the status of the pathologist as a specialist and consultant, and by a comprehensive plan of cooperation between the hospital and the local physicians. The laboratory of the hospital could be made the center of all laboratory work of the members of the medical profession of the entire community. Under such conditions a financial arrangement could be made that would be satisfactory to the hospital and to the pathologist.

The pathologist of every hospital and commercial laboratory should have a license to practice medicine because (1) he is practicing medicine just as much as any other specialist (2) it will place him on a legal equality with all licensed clinicians and specialists, and (3) it will insure him certain legal rights and privileges and the opportunity to perform certain professional duties such as qualifying as an expert witness, which only a license to practice can supply. The enactment of new laws appears to be unnecessary.

The Anesthetist

DR. F. H. McMECHAN, Rocky River, Ohio. The code of medical ethics has come to me representing the third generation of Ohio doctors in my family, as a sacred heritage, and an experience of thirty years in anesthesia has convinced me that anesthesia must be limited to licensed and qualified physicians to achieve its destiny—the conquest of human pain.

Anesthesia was the gift of pioneer doctors and dentists to suffering humanity and every significant advance in its science and practice has been contributed by doctors, dentists and research workers of similar standing. In contrast, technicians have added nothing of any consequence. Anesthetics are among the most potent and dangerous drugs used in the practice of medicine; they penetrate to every cell and organ of the body and may cause almost instant or delayed death by their toxic effects. The dosage of general inhalation anesthetics cannot be prescribed in advance but must be determined from moment to moment during administration. The dosage of local and other anesthetics must be determined by the risk of the patient, the nature and duration of the operation to be done—certainly a challenge to the knowledge and experience of the keenest doctor. No patient should ever be given an anesthetic whose condition and risk has not been diagnosed in advance of the operation, so that every resource of medical science can be used to lessen the risk and make the recovery more assuring. Certainly in this preoperative evaluation and the selection of the safest anesthetic and best method of administration, the medical anesthetist is more in a position to act as a consultant than a technician.

By charting the pulse, respiration, blood pressure and all other available reactions of the patient, the medical anesthetist continuously diagnoses the changing condition of the patient to regulate the anesthetic, to warn of any impending dangers and to combat complications. The surgeon is not in a position to do this for himself or the technician while operating, and the technician is certainly not capable of doing it. The safety first rules of the International Anesthesia Research Society require such diagnostic evaluation and charting by all medical anesthetists to prevent needless deaths.

The safety of the patient demands that the anesthetist be able to treat every complication that may arise from the anesthetic itself by the use of methods of treatment that may be indicated. The medical anesthetist can do this, the technician cannot. More recent developments have extended the field of medical anesthesia to include resuscitation, oxygen therapy and therapeutic nerve block for intractable pain, the treatment of various conditions of disease and the rehabilitation of the disabled—all fields of practice quite beyond the capacity of the technician.

The code of medical ethics of the British Empire removes any doctor from the medical register who uses any one but a doctor to give an anesthetic or who gives an anesthetic for any one but a registered doctor. Also the greatest medical organizations in the British Empire have recognized anesthesia as a specialty of medicine, by maintaining sections of anesthesia for many years. As a result every medical school teaching and voluntary hospital and nursing home in the British Empire and its dominions has its full quota of exceedingly competent medical anesthetists, all of whom must face a coroner's inquest for every death under anesthesia. Great Britain tried out technician anesthesia just once during the war emergency on account of the tremendous shortage of doctors, but the Society of Coroners discontinued technician anesthesia at the close of the war as too dangerous to public safety in times of peace.

For years organized medical anesthesia in the United States has been as nation wide and progressive as in the British Empire and has now reached the point of the certification of medical anesthetists as specialists and the founding of a college of anesthetists. Minimum standards for approved medical schools require basic science, didactic and clinical teaching and experience in anesthesia. Minimum standards for approved hospitals require that a qualified medical anesthetist must be in charge of the department of anesthesia and maintain that anesthesia is a medical specialty. Although medical anesthesia has reached such a point of achievement that anesthetists from all parts of the world now come to the medical anesthetists of the United States for the latest advances in the specialty, the more extended and rapid development of anesthesia within the profession can be fostered only through medical and not through technician anesthesia.

In those medical schools, teaching hospitals and clinics in which technician anesthesia has been in use, only certain limited routine methods have been entrusted to technicians, all other methods being restricted to surgical specialists or medical anesthetists, plainly an indication that technician anesthesia cannot possibly deliver a complete anesthesia service. Legally even such technician anesthesia must be "supervised" by the operator. Certain medical schools and hospitals are maintaining technician anesthesia schools on the basis of technician teaching and competence. In doing this is not the profession again creating the same sort of "diploma mills" in the practice of medicine that it has spent so many years in abolishing? While the medical anesthetist, practicing as a specialist, is personally legally responsible for negligence, accidents or fatalities under his administration and during recovery, "supervised" technician anesthesia makes either the surgeon or the hospital or both legally liable for damage suits in the same circumstances. Such damage suits are becoming more and more numerous and damages have been awarded in most of them.

The medical profession has the protection of court decisions holding that the license to practice is a "property right" under the constitution. Is the profession prepared to sacrifice this protection by delegating the disposal of this "property right" to the "supervised" or "corporation" practice of medicine? "Supervised" technician anesthesia is the first big inroad of socialized medicine on the economic level of technician pay and standards. It also means the "corporation" practice of medicine by hospitals and hospital associations under layman control. This is shown in the fact that the recently formed association of technicians was founded by one of the largest hospital associations and the member technicians are known as "hospital anesthetists" indicating absolutely "socialized" practice and "corporation" domination. If the "property right" to practice medicine is not upheld as interpreted by West Vir-

gma, Indiana and California and safeguarded by the profession, the socialization and corporatization practice of radiology, pathology and anesthesia will be the future fate sharing all other specialists, including surgeons, in the face

Pressure from hospitals and hospital associations has induced the profession to use the technician in limiting opportunities in many lines of medical practice. This is forcing more and more doctors to go into the surgical specialties to make a living. Further overcrowding and technician invasion will inevitably destroy surgery itself economically. The economic factor responsible for 25,000 too many doctors is the fact that 25,000 technicians are practicing "socialized and corporatization medicine."

Surveys have shown that 50 per cent of three year trained nurses disappear entirely from nursing within two years after graduation and 85 per cent within five years. This involves a labor turnover and replacement that would economically wreck the greatest industries in the United States and it accounts in great measure for a large share of the annihilating overhead and deficits of the present hospital system. The technician in anesthesia is a part and parcel of this vanishing personnel and represents an economic liability. By contrast the physician devotes a lifetime's career to developing himself, hospital anesthesia service and cooperation in the advancement of the surgical specialties. He is one of the hospital's most permanent economic assets. Millions of anesthetics must be given every year. If any great industry had such a staple product as painless surgery, it would certainly use the best obtainable experts in marketing such a boon to suffering humanity. I leave it to your judgment whether the greatest number of satisfied patients can be made through supervised and "corporation" technician anesthesia or through licensed and highly qualified medical anesthetists.

The Surgeon

DR KARL A. MEYER Chicago. No surgeon who is worth his salt as a surgeon can be an expert radiologist and an expert pathologist also and at the same time administer his own anesthetics. Of the radiologist he must ask technical perfection in the management of x-rays, fluoroscopies and roentgen therapy and a penetrating analysis in the interpretation of roentgenologic results. A well trained technician can usually take excellent roentgenograms as long as the pictures do not deviate from the standard routine.

Several recent advances in roentgenography depend on the parenteral injection of contrast mediums. This should not be entrusted to any one but a licensed physician who would understand the action of drugs and the reaction of patients and be able to act promptly in any emergency. The surgeon would then have to do these injections himself. This would not only tie him up in his work considerably but unless the organ in question was the surgeon's special field it is probable that his handling of the injection would be less skilful than that of the competent general radiologist.

Fluoroscopies are certainly outside the province of a technician. The incidence and location of lesions, their usual progress and spread, the movements of the heart and lungs, the physiology of the gastro-intestinal tract, the space relations within the body and deviations from the normal are far outside his ken unless he knows anatomy, physiology and pathology, and if he does then he is a doctor and not a technician. The surgeon who is primarily a therapist can rarely develop more than a cursory knowledge of fluoroscopy even in special fields and in any case must always have available some one on whose radiologic ability in other fields he can depend.

Roentgen therapy cannot be entrusted to a technician. The treatment of neoplasms for example requires a fine balance of judgment between effective dosage to stop the growth and limits of tissue tolerance to prevent violent local and general reaction. It requires a profound understanding of the pathogenesis of lesions and a wide experience in their sensitivity. These attributes can be found only in a man with medical training.

The greatest need which the surgeon has of the radiologist is in the field of diagnosis. For the major portion of questionable borderline and unusual cases the cases in which x-rays are

really needed, the surgeon must have the cooperation of an expert radiologist. Roentgenography is not photography. Only a physician practicing radiology would know where the normal suture lines are, where skull fractures are most likely to occur, and that the fracture line might not be visible for ten days after a head trauma. Only such a man could differentiate between osteomyelitis and early or unusual sarcomas of bone, could evaluate properly the amount of normal fibrosis in a lung or the width of an arteriosclerotic aorta or could manipulate a patient to fill lung cavities with iodized oil or gastro-intestinal diverticula with barium sulphate. Were radiology left to men without a complete medical training, research in this field would stop. Progress depends not on technical perfections but on intimate correlations between the roentgenogram and the patient, which can be discerned only by one trained in handling both.

The practice of pathology should also, from the point of view of the surgeon, be limited to those licensed to practice medicine. The surgeon cannot possibly keep up with the literature and changes in all these fields and must have some one on whom he can rely. The performance of autopsies is vital to the prevention of repeated mistakes in surgery. This cannot be left to a technician; the interpretation of autopsies requires a high grade intellectual activity and experience which is impossible to attain by any one who has not had a complete medical education. The surgeon himself could not and, if he could, should not perform these autopsies, because, even if he wears rubber gloves, cadaver contamination is so difficult to avoid and so difficult to get rid of that it is unjust to his patients for him to permit himself to do autopsies. It would take almost three days to resterilize his hands after such a contact. Therefore he has no right to engage in autopsies.

Anesthesia stands in a somewhat different relation to the surgeon than does radiology or pathology. The research work in the development and perfection of anesthetics and the institution of the unusual or difficult anesthetics must be left to the physiologic, pharmacologic, anatomic and surgical fields of medicine. The actual administration of the ordinary anesthetics, however, is not a highly skilled interpretative science like radiology or pathology, but a relatively noncomplicated though highly skilled, technical procedure. It would perhaps be ideal to have all anesthetics administered by medical men. Difficulties stand in the way. Administering an anesthetic takes even more time than the surgery. The patient would therefore have to pay an anesthetic fee comparable to the surgical fee. Under present economic circumstances the medical men who go into the administration of anesthetics do so (with certain brilliant exceptions) either as a temporary expedient or because they cannot get into anything else. I venture to say that under these circumstances a conscientious technician devoting a lifetime to the field would probably serve better for the routine anesthetics than a medical dilettante in anesthesia. The surgeon cannot always be with the radiologist or the pathologist. In his work he is constantly with the anesthetist, assumes full responsibility for the anesthetics, can institute the special spinal and intratracheal anesthetics himself and can closely supervise the conduct of the anesthesia throughout its course. For these reasons from the standpoint of the surgeon, anesthetics can be administered by well trained technicians but radiology and pathology must be limited to those licensed to practice medicine.

The Internist

DR JAMES S. McLESTER, Birmingham Ala. The internist is a general practitioner among specialists. He is the one physician who examines the patient as a whole. He it is who pieces together the parts contributed by the several specialists, considers each feature, gives it proper place and emphasis, and then endeavors to envisage the whole. Of great importance to him is the work of the radiologist and the pathologist. He may not be entitled to an opinion regarding the anesthetist but of the qualifications of these two he can speak his mind freely.

In the last analysis this is a question of education, not merely one of licensure. The license is simply a certification by the state that the holder has been examined and found to have the educational and other qualifications necessary for the practice of medicine. The question, then, is: Shall the educational qualifications demanded of the physician in practice be required also

of those who would limit their work to radiology and pathology? Believing in the profound influence of education on a person's ability to observe accurately and to reason soundly, I answer Yes

The practice of radiology involves three things (1) the making of roentgenograms, (2) the description and interpretation of what is seen in the roentgenogram and in the fluoroscope, and (3) treatment by means of radiation. The first of these can be dismissed from this discussion if that were all, radiology could be practiced by any well drilled technician, no matter what his education. For the other two functions of the radiologist the demands are entirely different. For the interpretations expected of the radiologist, a broad educational background is required. He should have a knowledge of anatomy and physiology and equally important a good conception of the diseases of which he would give a radiographic description. It is not asked that he make the diagnosis. True, he sometimes, without adequate description, does this, but that is not what is asked. It is requested of him that he observe accurately, describe faithfully what he sees and then in suitable instances, as one feature of the clinical picture offer his own interpretation. This demands an intimate knowledge of clinical problems. The other part of his work, the application of radiotherapy, demands greater judgment than is required in any other field of therapeutics. The type of treatment needed the bodily areas to be exposed, the length and frequency of such exposure and the dosage are best determined after mature judgment the kind of judgment that comes of a well trained intellect. Without this, irreparable harm may be done. To have the special knowledge required and the ability to bring to bear on the task the proper judgment, the radiotherapist should enjoy a type of learning and an intellectual background that come only from a broad well rounded medical education. As for the pathologist is there any reason why his education should be more restricted than that of other physicians? No one will deny that the pathologist should be broadly educated.

There is another light in which the educational qualifications of both radiologist and pathologist should be viewed, that is, the light of research. If the rapid advances made in medicine during the last few decades are to progress at full speed, the contributions of radiology and pathology must continue, and these can come as a rule only from men of broad caliber. Medical licensure was devised by the state to protect the public from the incompetent practitioner. Is the radiologist or the pathologist, when incompetent, capable of harm? Yes. This being true, the state should properly require of the radiologist and the pathologist a certificate of competence. This certificate is called a license.

(To be continued)

MEDICAL BROADCASTS Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45 central standard time (May 2 and May 9, 4:30 Chicago daylight saving time, 3:30 central standard time). The next three broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

April 25	May Day or All Year Round?
May 2	Being Your Age
May 9	Saving Our Mothers

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15 central standard time (May 7, 4 o'clock Chicago daylight saving time, 3 o'clock central standard time). The next three broadcasts will be as follows:

April 23	Sudden Death Morris Fishbein M.D.
April 30	Child Health W. W. Bauer M.D.
May 7	Mothers of America W. W. Bauer M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Bill Introduced—A 2401 proposes to regulate the conduct of pounds and to regulate the disposition of animals impounded or sheltered therein. This bill specifically makes it unlawful for any pound master to permit any live animal in his custody to be used for experimental purposes or to turn over any animal in his custody to any person, school, university, research laboratory or experimental station to be used for educational demonstration or medical, scientific or experimental purposes.

Society News—Speakers before the Alameda County Medical Association, March 18, included Drs. Edward H. Ryerson, Rochester, Minn., on "Recent Concept and Treatment of Diabetes"; Dr. Esmond R. Long, Philadelphia, among others addressed the California Tuberculosis Association in Long Beach, March 29-30, his subject was "The Chemistry of the Tubercle Bacillus". Dr. Long was the principal speaker at the annual banquet, he talked on "Tuberculin in the Epidemiology, Diagnosis and Treatment of Tuberculosis".

Dr. Anrep Gives Lane Lectures—Dr. Gleb V. Anrep, professor of physiology, Egyptian University Medical Faculty, Cairo, Egypt, will deliver the twenty-fifth course of Lane Medical Lectures, April 22-26, in Lane Hall, Stanford University School of Medicine, San Francisco. The titles of Dr. Anrep's lectures are:

The Proprioceptive Mechanism of Cardiovascular Regulation
The Central and Reflex Respiratory Regulation of the Heart Rate
The Coronary Circulation
The Circulation in the Voluntary and Plain Muscles in Relation to Their Activity

Resolutions on Communicable Disease—At a special meeting, April 4, the advisory committee to the San Francisco department of public health on acute anterior poliomyelitis adopted resolutions declaring its attitude on the use of poliomyelitis vaccine and on other types of immunization. The committee urged the director of public health, Dr. Jacob C. Geiger, to take no active stand favoring the use of vaccine for poliomyelitis until its value has been more fully demonstrated. It was recommended that experimental administration be restricted to properly qualified research institutions. Scarlet fever immunization should not be approved the committee advised, even though the disease is becoming more endemic in the city and county. With respect to diphtheria it was recommended that children be immunized at the age of 1 year, and it was further pointed out that this procedure was the responsibility of the physician in charge of the infant at the time. Members of the committee include Karl F. Meyer, Ph.D., and Drs. William P. Lucas, Edward B. Shaw, Harold K. Faber, James W. Ward and Isaac W. Thorne.

COLORADO

Joint Tuberculosis Meeting—The Colorado Tuberculosis Association, the El Paso County Sanatorium Association, the Denver Tuberculosis Society and the Denver Sanatorium Association held a combined meeting in Denver, April 4. Speakers included Drs. Oscar S. Levin on "Causes of Death in Surgical Collapse of the Lung", Charles H. Boissevain, Colorado Springs, "Antibody Response to Different Derived Proteins of the Tubercle Bacillus", Harry J. Corper, Arthur P. Damerow and Maurice L. Cohn, Ph.D., "Recent Researches on Immunity to Tuberculosis". Dr. Esmond R. Long, director of the laboratory, Henry Phipps Institute, Philadelphia, gave an address entitled "Taking the Census in Tuberculosis".

Society News—Dr. Cyrus W. Anderson, Denver, presented a paper on "Physiology and Fertilization of the Human Female," before the Northeast Colorado Medical Society, February 17, in Sterling. At a meeting of the Pueblo County Medical Society, February 19, Dr. Solomon W. Schaefer, Colorado Springs, discussed problems in tuberculosis, and Dr. William F. Singer, Pueblo, treatment of infections. The San Juan Medical Society was addressed in Durango, January 13, by Dr. Emil E. Johnson, Cortez. A symposium on cancer in the intestinal tract was presented before the San Luis Valley Medical Association, February 22, by Drs. Royal H. Finney, George A. Unfug, Paul M. Ireland and Carl W. Maynard, Pueblo. At a meeting of the Medical Society of the City and County of Denver, March 19, Drs. Alfred R. Masten

Whit Ridge discussed "Value of the Red Cell Sedimentation Test with Special Reference to Tuberculosis," and James R. Jaeger, "Intracranial Injection of Air for Treatment of Head Injuries."

DISTRICT OF COLUMBIA

Medical Bills in Congress—H. R. 7295 introduced by Representative Quinn Pennsylvania proposes to prohibit experiments on living dogs in the District of Columbia for any purpose other than the healing or curing of the dog. S. 2013 has passed the Senate directing the Commission on Licensure to Practice the Healing Art in the District of Columbia to issue a license to practice the healing art to Dr. Pak Chue Chan.

Annual Scientific Meeting—The annual scientific assembly of the Medical Society of the District of Columbia will be held May 1-2. Out of town speakers will include Drs. John Shelton Horsley, Richmond Va., on 'The Incidence, Diagnosis and Treatment of Cancer of the Stomach' and Sam Weiss, Boston, on 'Syncope.' Other physicians on the program will be

Jerome F. Crowley, Endometriosis
Frank J. Eichenlaub, Management of the Syphilitic Patient
William B. Marbury, Lymphogranuloma Inguinale with Special Reference to Stricture of the Rectum
Paul S. Putzki, Resume of Acute Appendicitis in Washington Hospitals for a Period of Two Years
William H. Wilmer, Diagnosis and Treatment of Ocular Tuberculosis
John H. Ivons, Abdominal Symptoms in Diabetes Mellitus
Francis R. Wagner, Pelletis of Pregnancy
Howard F. Kane, subject not announced
John Minor, The Systematic Diagnosis of Anemias
Stuart O. Foster, The Present Status of the Treatment of Secondary Anemia
Bernard W. Leonard, The Size and Shape of the Heart
George R. Hufman, Erythremia with Emphasis on Treatment.
John A. Talbot, Fractures
Edwin Kirby Smith, Factors in the Care of Premature Infants
Antoine J. Schneider, Myasthenia Gravis and the Myopathies
Arthur M. Zinkhan, Clinical versus X-Ray Diagnosis of Sinusitis
Ralph R. Bett, Roentgen Treatment of Chronic Sinus Disease with Roentgen Rays

In addition physicians participating in clinics include Drs. William Ross Morris, James A. Cahill Jr., Charles Stanley White, Joseph P. Shearer and Harry Hyland Kerr. Charles P. Cake, Sara E. Branham, Walter K. Myers, Ella M. A. Enlows and Eugene Clarence Rice Jr. A complimentary luncheon will be held at the Mayflower Hotel with Edmund A. Walsh, S.J., as the guest speaker, he will discuss 'Soviet Medicine.' Dr. George C. Ruhlman, district health officer, will address a public meeting Wednesday evening, and the annual banquet will be held Thursday evening. Motion pictures will be shown continuously.

FLORIDA

Bill Introduced—S. 2 proposes to provide for a system for compensating workmen for injuries arising out of and in the course of their employments and for such diseases or infections as naturally or unavoidably result from such industrial injuries. The employer is to furnish medical, surgical and other remedial treatment, nursing and hospital service, medicine, crutches and apparatus for such period as the nature of the injury or the process of recovery may require. Only in the event that the employer fails to furnish these services after request by the workman, is the workman to be allowed the privilege of selecting his own physician.

ILLINOIS

Bill Introduced—S. 257 proposes to require all persons licensed to practice any form of the healing art to register annually with the director of registration and education and to pay an annual renewal fee of \$1.

Scarlet Fever Prevalent—With more than 12,000 cases of scarlet fever and 175 deaths reported since the first of the year, the state department of health announces the greatest wave of scarlet fever and sore throat ever recorded in the state. It was said that about 200 new cases are being reported daily.

Society News—Dr. Don C. Sutton, Chicago, addressed the Peoria City Medical Society April 2 on 'Heart Disease Complicated by Pregnancy.'—Dr. Ralph A. Kinsella, St. Louis, discussed 'Streptococcal Infection' before the St. Clair County Medical Society in East St. Louis, April 4.—A symposium on obstetrics was conducted before the Adams County Medical Society, Quincy, April 8 by Drs. Ralph McReynolds, Henry J. Jurgens, Clarence A. Wells, Milton E. Bitter and Norbert A. Blickhan, Quincy.

Chicago

Personal—Eugene R. Schwartz, superintendent of registration for the state department of registration and education died, April 10, of complications that followed an operation for

gallstones, according to the *Chicago Tribune*.—Dr. Lowell T. Coggeshall, instructor in medicine, University of Chicago, has been appointed a member of the International Health Division of the Rockefeller Foundation, effective in July.

Study of Premature Births—The Chicago Health Department made a study of the death certificates of infants born and dying in hospitals having more than 200 births a year, which shows that the death rate of premature infants under 15 days of age was as low as 5 per thousand births in some institutions and as high as 50 per thousand births in others. The low death rate in some hospitals was attributed to three requirements:

1 The newborn infant is scrupulously protected against chilling from the moment of birth. Incubator facilities maintained at a proper temperature are constantly available for these infants and weak infants are not oiled or bathed until this seems safe.

2 Attendants are trained in proper methods for resuscitation. Small caulkers and oxygen are always available. Undue trauma is avoided.

3 Every effort is made to obtain breast milk until the mother's milk is available and an effort is made to stimulate the mother's breast by manual expression.

Hospitals in which the death rates are high from prematurity are found to be failing in one or more of these essentials. To help meet this problem the department of health has established a twenty-four hour incubator ambulance service for hospitals that do not have incubator facilities and for private physicians delivering mothers in the home.

INDIANA

Personal—Dr. Eugene F. Kratzer, Kokomo, was presented with a quilt at a dinner in his honor, February 27, to observe his completion of twenty-five years practice in the community. The quilt bears the embroidered names of many children whose births the physician attended.—Dr. Floyd L. Grandstaff, Decatur, was named health officer of Adams County, March 5, succeeding the late Dr. John W. Vizard.

Pediatricians Organize—The Indiana Pediatric Society was organized at a meeting in Indianapolis, March 13. Officers elected are Drs. Louis H. Segar, clinical professor of pediatrics, Indiana University School of Medicine, Indianapolis, as president; Reuben A. Craig, Kokomo, vice president, and Matthew Winters, associate professor of pediatrics at the university, secretary.

Society News—Dr. Charles O. McCormick, Indianapolis, addressed the Hamilton County Medical Society in Carmel, March 12 on 'Maternal Mortality.'—The Hancock County Medical Society heard Dr. C. O. Richey, Indianapolis, discuss 'Respiratory Disturbances' at a meeting in Greenfield, March 18.—At a meeting of the Tippecanoe County Medical Society in Lafayette, March 14, Dr. Walter Dean, Louisville, Ky., spoke on the eye, ear, nose and throat.—Dr. William E. Barnett, Logansport, discussed 'Circulatory Failure' before the Henry County Medical Society in Newcastle, March 14.—Dr. Edmund M. Van Buskirk, Fort Wayne, was elected president of the Indiana Roentgen Ray Society in Indianapolis, February 26.

IOWA

Bill Enacted—S. 20 has become a law, requiring all applicants for licenses to practice any form of the healing art as a condition precedent to their right to examination by their respective professional boards, to pass examinations in anatomy, physiology, chemistry, pathology, bacteriology and hygiene, to be given by an impartial basic science board.

Society News—Dr. George V. I. Brown, Milwaukee, will address the Linn County Medical Society, Cedar Rapids, May 2 on 'Plastic Surgery, the Child of General Surgery.'—A symposium on acute infectious diseases was presented before the Des Moines Academy of Medicine and the Polk County Medical Society, March 26 by Drs. Harold J. McCoy, Arnold M. Smythe, Herman J. Smith and Harold C. Bone.—Dr. Jennings C. Litzberg, Minneapolis, addressed the Johnson County Medical Society in Iowa City, April 3, on 'Toxemias of Pregnancy.'

Tuberculosis and Heart Associations Meet—The annual meeting of the Iowa Tuberculosis and Iowa Heart associations was held at the Hotel Fort Des Moines, March 22, in Des Moines. Symposia made up the greater part of the program. At a luncheon meeting the speakers were Drs. Walter L. Biering, Des Moines, President American Medical Association and George E. Fahr, professor of medicine, University of Minnesota School of Medicine. Dr. Fahr's subject was 'A Clinical Evaluation of the New Cardiology.' Dr. William W. Bauer, Chicago, addressed the annual dinner on 'The Bird with a White Breast.'

KANSAS

Porter Lectures—Edward A. Doisy, Ph.D., professor of biochemistry, St. Louis University School of Medicine, St. Louis, will deliver the Porter Lectures of the University of Kansas, April 23-24. The titles of the lectures are

The Ovarian Follicular Hormone and Related Compounds
Sex Hormone Therapy from the Experimental Viewpoint
Some Aspects of the Study of Internal Secretions

The first two lectures will be given in Kansas City and the last at the main university in Lawrence. The annual series of graduate clinics has been arranged for April 22-24 to enable practicing physicians of Kansas and adjoining states to attend Dr. Doisy's lectures.

LOUISIANA

State Medical Meeting in New Orleans—The fifty-sixth annual meeting of the Louisiana State Medical Society will be held in New Orleans, April 29-May 1, with headquarters at the Roosevelt Hotel and under the presidency of Dr. Chaillé Jamison, New Orleans. Dr. Stanhope Bayne-Jones, dean, Yale University School of Medicine, New Haven, will deliver the annual oration on "The Influence of the State on Medical Education." A public meeting, Monday evening, will be addressed by Drs. Frederic J. Mayer, Opelousas, on "The Louisiana System of Public Hygienic Education"; Thomas J. Perkins, Simmesport, "Importance of Mental Hygiene to the General Practitioner"; Robert W. Todd, New Orleans, "Effectiveness of Typhoid Vaccine in the Control of Typhoid Fever"; William H. Perkins, New Orleans, "Who is to Blame for Cancer Deaths?"; and John Signorelli, New Orleans, "Toxoid Immunization." The New Orleans Campaign for Diphtheria Eradication. Other physicians on the program include

Lionel J. Bienvenu, Opelousas, "Caisson and Pseudo-Caisson Disease"; Joseph M. Perret, New Orleans, "Tularemia"; Harris Hosen, New Orleans, "The Bacteriophage in Respiratory Disease"; Edmund McC. Connely, New Orleans, "Uses of Hypnosis in Psychotherapy"; William R. Mathews, Shreveport, "Pathology of Sickle Cell Anemia with Brief Clinical Considerations"; William H. Browning, Shreveport, "Common Manifestations of Gastrointestinal Food Allergy"; Louis J. Dubos, New Orleans, "Digitalization in Cardiac Failure"; H. Guy Riche, Baton Rouge, "Heart Disease in Middle Life"; Charles J. Bloom, New Orleans, "Autogenous Vaccine Therapy in Pediatrics"; Herbert R. Unsworth, New Orleans, "Dementia Praecox"; Urban Maes, New Orleans, "Pathologist's Part in Malignant Disease from the Surgeon's Point of View"; Donovan C. Browne, New Orleans, "Early Diagnosis of Carcinoma of the Colon and Rectum"; Roy Carl Young, Covington, "Chronic Epidemic Encephalitis: Report of Eleven Cases with Alcoholism as Outstanding Symptom"; Charles A. Thomas, Tucson, Ariz., "The Collapse Program of Advanced Pulmonary Tuberculosis"; Curtis H. Tyrone, New Orleans, "Vaginal Hysterectomy".

MAINE

Bills Enacted—The following bills have become laws: S. 714 amending the chiropractic practice act by (1) requiring applicants for licenses to be graduates of chiropractic colleges which, as a condition precedent to their graduation, require personal attendance and completion of a course of four school years of not less than six months each and a total of 2,600 sixty-minute school hours and by (2) requiring licentiates to register annually with the board and to pay an annual fee of \$3, and H. 1838, limiting the sale of sanitary or prophylactic rubber or other articles for the prevention of venereal diseases, to licentiates of the state bureau of health.

MISSISSIPPI

Lectures on Obstetrics—Dr. Maxwell E. Lapham, Jackson, is conducting a series of graduate lectures in obstetrics in several counties of the state. Each meeting is devoted to about one hour for lectures and one hour for clinical demonstrations. In addition to Dr. Lapham, who is the field clinician, the committee on postgraduate medical education is participating. This committee is made up of two members each from the Mississippi State Medical Association, Tulane University of Louisiana School of Medicine and the state board of health and one representative from the Mississippi State Hospital Association. The next circuit of lectures is planned for the areas surrounding Cleveland, Clarksdale, Greenville, Rolling Fork and Yazoo City. Dr. Lapham conducted similar courses in Virginia in 1933 and 1934.

NEVADA

Bill Enacted—A. 260 has become a law, creating a board to arrange for and to supply necessary maintenance, medical and surgical treatment, and hospitalization to indigent expectant mothers.

NEW HAMPSHIRE

Delegates Oppose Compulsory Health Insurance—The house of delegates of the New Hampshire Medical Society held a special meeting, March 7, in Concord to consider the report of the meeting of the House of Delegates of the American Medical Association in Chicago, February 15-16. A resolution was adopted approving the action of the national association, opposing compulsory health or sickness insurance or other medical services under governmental control or lay supervision and approving voluntary plans for medical service under medical supervision. Copies were sent to all representatives in Congress.

NEW JERSEY

Personal—Philip R. White, Ph.D., for the past two years fellow of the Rockefeller Institute for Medical Research, New York, has been appointed to the staff of the department of animal pathology of the Rockefeller Institute at Princeton. Dr. Arcangelo Liva, Hackensack, has been awarded the honorary degree of doctor of medicine by the University of Rome, according to the *Bulletin* of the Bergen County Medical Society.

Society News—Dr. Pol N. Coryllos, New York, addressed the Atlantic County Medical Society, Atlantic City, March 8, on "Pathogenesis, Mechanism and Treatment of Tuberculous Cavities."—Drs. Nathan Rosenthal and Allen O. Whipple, New York, addressed the Bergen County Medical Society, Hackensack, March 12, on "Blood Dyscrasias in Children" and "Splenectomy," respectively.—Drs. William H. Park and Maurice Brodie, New York, addressed the Essex County Medical Society, Newark, March 14, on "The Newer Preventives of Diphtheria: Precipitated Toxoid and Toxoid Flocculi" and "Immunization Against Poliomyelitis," respectively.—Drs. Raymond J. Connors and Anthony Bassler, New York, addressed the Hudson County Medical Society, March 5, on "Pilonidal Sinus" and "Chronic Colitis from the Practitioner's Standpoint," respectively.

NEW YORK

Bills Introduced—S. 2032 and A. 2455 propose to exclude from private and public schools children not immunized against diphtheria. A. 2458, to amend the law in relation to certificates of birth, proposes that, if a child is born out of wedlock, the name of the putative father shall not be entered on the birth certificate without his consent. If the putative father does not consent, the physician or the midwife, with the consent of the mother, is to supply at least two given names for the child, one of which shall serve as a surname except that the name of any known living male is forbidden. The mother may also use the last given name as her name.

Personal—Dr. N. Stanley Lincoln, Albany, who was provisionally appointed superintendent of the Hermann M. Biggs Memorial Hospital at Ithaca, has been transferred to the superintendency at the new tuberculosis hospital at Mount Morris. It is expected that the Mount Morris building will be ready for occupancy this month, while that at Ithaca will not be finished until late in the year because of delays in construction.—Dr. Leon A. Chojnacki, Perysburg, was appointed clinic physician in the division of tuberculosis of the state department of health, March 1.—Dr. Blakely R. Webster has been appointed superintendent of Dannemora State Hospital, Dannemora, succeeding Dr. Charles M. Burdick, who retired several months ago.—Dr. Frederick F. Russell, director of the International Health Division of the Rockefeller Foundation, delivered the Eastman Memorial Lecture at the University of Rochester School of Medicine and Dentistry, March 21, on "The Continuing Need for Research in the Field of Public Health."

New York City

Conference on Chronic Tuberculosis—The Tuberculosis Sanatorium Conference of Metropolitan New York sponsored a clinical conference on chronic pulmonary tuberculosis at Cornell University Medical College recently. Speakers were Drs. Edgar Mayer and William De Witt Andrus, on "Bronchiectasis and Cystic Disease of the Lung" and "Present Status of Phrenic Nerve Interruption," respectively. Cases from the New York Hospital pulmonary service were presented.

Symposium on Headache—A symposium on headache was presented at the stated meeting of the New York Academy of Medicine, April 4, with the following speakers: Drs. James W. Babcock II, on "The Role of Diseases of the Nasal Accessory Sinuses in Headache"; Webb W. Weeks, on "Ocular Headache"; Alexander Lambert, on "Tobacco and Drugs as a Cause of Headache"; Frederick Tilney, on "Causes of Headache in General and as a Symptom of Tumors and Other Diseases of the Brain"; and Foster Kennedy, on "Drugs and Other Methods of Treatment."

Personal—Dr David J Kaliski has been made a Chevalier of the Legion of Honor by the French government. Dr Kaliski is a former president of the Medical Society of the State of New York and chairman of the coordinating council of the five county medical societies of New York.—Dr George H. Reichers, chief surgeon at Bushwick Hospital was guest of honor at a dinner given by members of the medical and nursing staffs and other friends March 14 at the Hotel Grand. The occasion marked his thirty-fifth anniversary as a physician and twenty-two years' service at the hospital. Dr William E. Lippold was toastmaster.—Dr Harry Plotz formerly of New York and now director of laboratories at the Pasteur Institute, Paris has recently been honored by the French government by advancement from the rank of Chevalier to Officer of the Legion of Honor of France.

NORTH CAROLINA

Bill Introduced—H 996 proposes to authorize Cabarrus County to establish and maintain a public hospital. Among other things the bill proposes that in the management of the hospital no discrimination is to be made against practitioners of any school of medicine or allied occupations recognized by the laws of the state and that all legal practitioners shall have equal privileges in treating patients in such hospitals. A patient is to have the absolute right to employ at his own expense his own physician. Such physician is to have exclusive charge of the care and treatment of the patient and hospital nurses as to such patient are to be subject to that physician's directions.

OHIO

Bill Passed—H 163 has passed the house, proposing to repeal the laws regulating the sale, distribution or possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

Executive Secretary Resigns—Don K. Martin executive secretary of the Ohio State Medical Association for sixteen years resigned March 15 to become manager of the Ohio Manufacturers Association. Mr. Martin was also general counsel for the association and editor-manager of the *Ohio State Medical Journal*.

Rabies Prevalent Among Dogs—Ohio is experiencing an outbreak of rabies in dogs in southern counties. *Ohio Health News* reports. From Jan. 1, 1934 to March 15 of this year the laboratory of the state department of health examined 1922 specimens and found 416 positive, 105 from one county alone. Only 430 specimens were examined in 1933. During the last ten years, fifty-eight persons have died of rabies in Ohio.

Society News—Dr Wells H. Teachnor, Columbus, addressed the Summit County Medical Society, Akron, March 5 on 'Diagnosis of Cancer of the Rectum and Colon'.—Dr Ralph H. Major, Kansas City Mo. addressed the Cleveland Academy of Medicine, March 15 on 'Some Aspects of Arterial Hypertension'.—Dr Cyrus E. Burford, St. Louis addressed the Toledo Academy of Medicine February 1, on tuberculosis of the genito-urinary tract. Dr Burford also participated in a clinic presented by the urologic department of St. Vincent's Hospital in the morning. Physicians from neighboring cities were invited. Dr Bert W. Culver, Coldwater, Mich., demonstrated a new appliance for treatment of hip fractures.

Personal—Dr Henry T. Sutton, Zanesville was entertained at a dinner at the Good Samaritan Hospital, Zanesville April 1 in celebration of his fiftieth anniversary in the practice of medicine. Dr Ward D. Coffman was toastmaster at the dinner which was sponsored by the Sisters of St. Francis at the hospital. Speakers were Drs William A. Melick, Cyrus M. Rambo and Edmund R. Brush, Zanesville; Joseph Price and Isaac B. Harris, Columbus, and Arthur L. Pritchard, Nelsonville. About fifty guests attended. Dr Sutton was the first health officer of Zanesville and one of the founders of the hospital according to newspaper reports. For several years he was a member of the state board of health. He was one of the founders of the Good Samaritan Hospital.

OKLAHOMA

Bills Introduced—H 90 proposes to accord to physicians, nurses and hospitals treating persons injured through the negligence of others liens on all rights of action claims judgments compromises or settlements accruing to the injured persons by reason of their injuries. S 285 proposes to require all applicants for licenses to practice any form of the healing art, as a condition precedent to their right to examination by their respective professional boards to pass examinations in

anatomy, physiology, chemistry, bacteriology and pathology to be given by a board of examiners in the basic sciences. This board is to consist of five members, members of the faculty of the state university, the state agricultural college, or some other state institution of learning in the state learned in the basic sciences and not engaged in the practice of the healing art.

PENNSYLVANIA

Bill Passed—H 1023 has passed the house and the senate, proposing to prohibit the sale or distribution of medicines, drugs or poisons by means of any vending machine or other mechanical device.

Graduate Conference at Wilkes-Barre—The staff of Mercy Hospital, Wilkes-Barre sponsored a graduate conference at the hospital, March 28. Guest speakers were Drs Pascal F. Lucchesi, Philadelphia, on 'Scarlet Fever', Elliott P. Joslin, Boston 'Treatment of Diabetes', John F. Erdmann, New York 'Tumors of the Breast' and John Cooke Hirst II, Philadelphia 'Active versus Conservative Management of Planned Deliveries'.

Economics Symposium—The Dauphin County Medical Society presented a symposium on medical economics at a meeting in Harrisburg, April 2, with the following speakers: Drs Harold A. Miller, Pittsburgh director, Pennsylvania State Emergency Medical Relief, 'Economic Trends in Medicine as Seen from Experience with Emergency Medical Relief', Arthur C. Christie, Washington, D. C., 'Complete Medical Care for All the People Without Health Insurance', and Francis R. Borzell, Philadelphia, 'Organized Medicine and Social Insurance'.

Philadelphia

Society News—Speakers at the meeting of the Philadelphia County Medical Society, March 27 were the following from Presbyterian Hospital, Columbia University, New York: Drs Allen O. Whipple 'Surgical Interference in Tumors of the Pancreas', Arthur H. Blakemore, 'Physiologic Aspects of Carotid Jugular Anastomosis' and George H. Humphreys, 'Cardiac Output Studies in Carotid Jugular Anastomoses'.—A symposium on 'The Problem of the Convalescent Patient' was presented before the Northern Medical Association of Philadelphia, March 18, by Drs William D. Stroud, Thomas A. Shallow and Michael A. Burns and Ann Laws Calley, R.N.—Drs Walter Freeman, Washington, D. C. and Bernard J. Alpers among others, addressed the Philadelphia Neurological Society, March 22, on 'Ventriculography with Thorotrast' and 'The Mental Syndrome of Corpus Callosum Tumors' respectively.—Dr Edward J. Klopp was recently elected president of the Philadelphia Medical Club.—Dr Russell L. Haden, Cleveland gave the Annual Conversational Lecture of the Pathological Society of Philadelphia April 11, on 'The Red Blood Cell in Man'.

RHODE ISLAND

Society News—Dr Thomas H. Lanman, Boston, addressed the Providence Medical Association, March 4, on 'Surgical Aspects of Pediatrics' and Dr Henry E. Utter, on 'Twenty-Five Years in Pediatrics'. Speakers at the meeting April 1 were Drs Francis H. Chafee on 'Medical Indications for Transfusions' and Jesse P. Eddy III, on 'Some Surgical Aspects of Blood Transfusions'.

Blood Donors' Bureau—The Providence Medical Association has established a bureau for professional donors of blood. All donors have negative Wassermann reactions and normal hemoglobin and are in good physical condition. Calls are handled through the Physicians and Surgeons Exchange. Dr Francis H. Chafee is chairman of the committee that arranged the service.

TENNESSEE

Bills Introduced—H 1092 and S 875 to amend the workmen's compensation act propose to compensate a workman for any injury or disease arising out of and in the course of the employment.

Society News—Dr Charles C. Vinsant, Maryville addressed the Blount County Medical Society April 11, on 'Common Diseases of the Anorectal Region'.—A symposium on diseases of the spleen was presented at a meeting of the Dyer Lake and Crockett Counties Medical Society, March 6 by Drs Joseph A. Crisler, Peter Whitman Rowland Jr and Russell A. Hennessey, Memphis.—Dr Charles R. Henry, Chattanooga, addressed the Chattanooga and Hamilton County Medical Society, April 4 on 'Oxygen Therapy in Pneumonia'.—Dr Gunnar Nystrom, professor of surgery, University of

Upsala, Sweden, addressed the Nashville Academy of Medicine, March 19, on "Public Medical Relief in Sweden."—Speakers at a meeting of the Black Patch Medical Society in Clarksville, March 20, included Drs Ernest W Goodpasture, on "Recent Advances in Study of Virus Diseases", Horton R Casparis, Nashville, "Nutrition of Infants and Children," and Beverly Douglas, "Skin Grafting"—Drs Kenneth F Maney, Charlottesville, and J Edwin Wood Jr, University, Va., addressed the Johnson-Sullivan Counties Medical Society, Kingsport, March 6, on rheumatic fever

WASHINGTON

Society News—The Spokane Surgical Society held its first annual meeting February 9, with Dr Waltman Walters, Rochester, Minn., as the guest speaker.—Drs Louis H Klemptner and Adolf J Drtina, Seattle, addressed the Skagit County Medical Society, February 25, on "Infectious Mononucleosis" and "Cardiography in Practice," respectively.—Speakers before the Walla Walla Valley Medical Society, February 14, were Seattle physicians Drs James M Bowers, Manford R Waltz and Oscar S Proctor, on diagnosis and treatment of diseases of the chest

WEST VIRGINIA

Personal—The Hancock County Medical Society gave a dinner in Steubenville, Ohio, recently complimenting Dr Fred B Harrington, Weirton, who retired as secretary of the society after twelve years in the office

Society News—Dr Isaac A Bigger, Richmond, Va., addressed the Harrison County Medical Society, February 7, on primary carcinoma of the lung Dr Rome H Walker, Charleston, president of the West Virginia Medical Association, and Mr Joe W Savage, executive secretary, also spoke.—Drs James S Klumpp and Walter C Swann, Huntington, addressed the Logan County Medical Society, Logan, February 13, on "Relation Between Pelvic Conditions and General Health in Women" and "Prevention of Coronary Occlusion," respectively.—Dr Chevalier L Jackson, Philadelphia, addressed the Ohio County Medical Society, Wheeling, February 15 on "Indications for Bronchoscopy"—Dr Fred W Rankin, Lexington, Ky., discussed "Selection of Peptic Ulcer Cases for Surgery" at a meeting of the Cabell County Medical Society, Huntington, February 14

GENERAL

Society of Neuropsychiatrists—The Southern Neuropsychiatric Association held its inaugural meeting in Memphis, Tenn., February 5-6 Dr Giles W Day, Galveston Texas, was elected president Dr William D Partlow, Tuscaloosa, Ala president elect, and Dr Newdigate M Owensby Atlanta, secretary The territory of the new association includes the states covered by the Southern Medical Association and membership is limited to 100 fellows and twenty-five members The next annual meeting will be held in New Orleans

National Academy of Sciences—Papers of medical interest to be presented at the annual meeting of the National Academy of Sciences at Washington, D C, April 22-24, include the following

Dr Eugene F Du Bois and James D Hardy New York Heat Losses from the Human Body

Dr William G MacCallum Baltimore Diabetes in Relation to the Anterior Hypophysis

John H Northrop, Ph D and Moses Kunitz Ph D Rockefeller Institute for Medical Research, Princeton N J Isolation from the Pancreas of a Substance Which Inhibits Trypsin Digestion and Its Effect on the Activation of Trypsin

Wintrop J V Osterhout Ph D and Samuel E Hill Ph D New York, Some Aspects of Anesthesia and Irritability

Drs Thomas M Rivers, New York and T F McNair Scott London England Meningitis in Man Caused by a Filtrable Virus

Dr George L Streeter Baltimore Significance of the Amnion

Miloslav Demerec Ph D Cold Spring Harbor N Y Relative Importance of Various Genes to the Organism

Federal Food, Drugs and Cosmetic Legislation—On April 1 the Copeland food, drugs and cosmetic bill, S 5, was made the unfinished business of the Senate and during the ensuing week the bill was discussed on the floor of the Senate in an effort to secure its passage After a full week's discussion and the adoption of numerous amendments, the senate, April 8, displaced the bill as the unfinished business by voting to take up another bill for consideration This action returns S 5 to the Senate calendar It was acquiesced in by Senator Copeland apparently to preclude a vote on a motion to recommit the bill to the Senate Committee on Commerce, made by Senator Bennett Champ Clark of St Louis County Missouri, who, with Senator Josiah W Bailey of Raleigh North Carolina, has vigorously opposed the enactment of the bill in its present form The bill has now lost its privileged status

Whether or not it will regain that status is problematic In any event, the outlook for the enactment during the present session of Congress of legislation needed for the protection of consumers of food, drugs and cosmetics is not promising

Change in Status of Licensure—The Illinois State Department of Registration took the following action, March 7

Dr Loring Brainard Palmer Atlanta Ga, license revoked for violation of Harrison Narcotic Act

Dr Nathaniel H Schaffner Chicago license restored it had been revoked Oct 6 1932 for violation of the Harrison Narcotic Act

The Massachusetts Department of Registration in Medicine reports the following

Dr Joseph N Tessier New Bedford, license revoked February 28 for gross misconduct in the practice of his profession

Dr Eli Silverman Boston license suspended for six months, March 14 because of deceit in connection with automobile accident insurance claims

Dr Joel Ginsburg Boston license suspended for one month March 14 because of deceit in connection with automobile accident insurance claims

American Chemical Society Program—At the spring meeting of the American Chemical Society in New York, April 22-26, the program of the division of medicinal chemistry will include the following addresses

Michael V Sullivan Ph D Washington D C Guanidines as Etiologic Factors in Pathologic Conditions

Dr Wolfgang F von Oettingen Cleveland The Development of Industrial Medicine with Special Reference to the Tasks and Problems of Industrial Toxicology

Michael Heidelberger Ph D New York Bacterial Proteins

Lyndon F Small Ph D Erich Mosettig Ph D Charlottesville, Va and Dr Nathan B Eddy Ann Arbor Mich Chemical and Pharmacologic Studies on Morphine Substitutes

Dr William P Murphy and Isabel Howard Boston, Some Effects of the Intramuscular Injection of a Concentrated Solution of Liver Extract

This meeting of the chemical society celebrates the tercentenary of the establishment of chemical industry in the United States, dating from the year in which Gov John Winthrop of Connecticut made a trip to England to consult with experts on the establishment of colonial industries and his first steps to carry out his plans In this connection George W Merck, president of Merck & Co, Rahway, N J, will give an address in the medical division on "Chemical Industry and the Medical Profession—A Mutually Advantageous Partnership" In addition, the division will join the division of biological chemistry in a symposium on vitamins

Medical Bills in Congress—Bills Introduced S 2472, introduced by Senator Long, Louisiana, proposes to pay an annuity to the widow of Dr Aristides Agramonte, of the Yellow Fever Commission H R 7158, introduced by Representative Taber, New York proposes to erect an addition to the veterans' facility at Canandaigua H R 7159, introduced by Representative Wadsworth, New York proposes to erect an addition to the veterans' facility at Batavia H R 7162, introduced by Representative Dear Louisiana, proposes to erect an addition to the veterans' facility at Alexandria, La H R 7174, introduced by Representative Plumley, Vermont, proposes to erect a veterans hospital in Vermont H R 7236, introduced by Representative Underwood, Ohio proposes to erect an addition to the veterans' facility at Chillicothe, Ohio H R 7287 introduced by Representative Jenkins, Ohio, proposes to reenact all public laws granting pensions to veterans and to dependents of veterans of the Spanish-American War, including the Philippine Insurrection and the Boxer Rebellion, and medical, hospital or domiciliary treatment to former members of the military or naval service, which were repealed by the act of March 20 1933 H R 7295, introduced by Representative Quinn, Pennsylvania, proposes to prohibit experiments on living dogs in the District of Columbia for any purpose other than the healing or curing of the dog H R 7375, introduced by Representative Underwood, Ohio, proposes to establish a Department of Veterans' Affairs and generally to revise the laws relating to veterans Among other things, the bill proposes to furnish domiciliary and hospital care, including medical treatment within the limits of department facilities, to any veteran of any war who is in need of hospitalization or domiciliary care and is unable to defray the expenses thereof, irrespective of whether the disability, disease or defect was due to service The bill further provides that the term "veteran" shall include any individual who served overseas as a contract surgeon of the army H R 7370, introduced by Representative Connery, Massachusetts, proposes to recognize the high public service rendered by soldiers who volunteered and served in trench fever experiments in the American Expeditionary Forces H R 7440 introduced by Representative Case, Massachusetts, proposes to erect an addition to the veterans' facility at Bedford, Mass H R 7455, introduced by Representative Evans, New York, proposes to authorize the appointment of registered pharmacists as first and second lieutenants in the Medical Corps of the Army and the Medical Officers' Reserve Corps

The Struggle of the Osteopaths for Registration

At the proceedings of the house of lords, before the select committee on the bill for the registration and regulation of osteopaths, an important witness for the applicants was Dr W K Macdonald, a qualified physician who practices osteopathy. He took his M D degree at Edinburgh and graduated as a doctor of osteopathy at Kirksville, Mo where he became a professor. He did not consider that osteopathy could yet be dignified by the term science, 'like medicine it was still an art'. Asked to describe the osteopathic lesion he said that it was not a dislocation but rather the complete or partial fixation of a joint within its normal range of movement accompanied by certain changes in the chemistry structure and function of the surrounding tissues. These lesions were either primary, being brought about by strain injury or bad posture or secondary, generally the result of nerve reflexes caused by some disturbance, abuse or disease condition of some part or organ. Osteopathic lesions were evidenced by inspection palpation and testing for passive movements in joints. They were so slight that few radiologists were capable of recognizing them unless specially trained. Asked about osteopathic research, he said that osteopathy was young. He did not claim that osteopathy could cure all diseases but that 'there is no disease acute or chronic, in which osteopathic treatment has not some important and irreplaceable part to play'. He was cross-examined by Sir William Jowitt the lawyer who appeared for the British Medical Association. He was asked whether the vast majority of scientific opinion in this country not merely that of physicians, was against the bill. He agreed but said that scientific men had not taken the trouble to investigate the claims of osteopaths. Had osteopathy no supporters among the scientists of the continent? He gave a similar answer. Asked what subjects in the medical curriculum he would omit in the training of osteopaths, he mentioned materia medica pharmacology and therapeutics. He also thought that a shorter course in bacteriology should be given. Also the practice of osteopathy should be substituted for the practice of medicine. Asked whether he would use antidiphtheric serum he said he would but that he would also treat the patient osteopathically. He admitted that in diphtheria the body does not provide adequately the healing power (this is contrary to the fundamental dictum of Still), also that in diagnosis there was no difference between osteopaths and physicians, but in a large number of cases of sickness it was impossible to make a diagnosis. There was disharmony in the body which preceded the recognizable effects of diseases and it was for evidences of this that osteopaths looked. Was typhoid caused by B typhosus? Yes, but if the bacillus obtained entrance into a healthy bowel there was less chance of disease. Had he any evidence that persons who escape are osteopathically sound? He had not. What was the osteopathic treatment of pernicious anemia? To treat any osteopathic trouble by manipulation of the spinal column and work on the nerve centers, which had been proved by experiments in the laboratory to have an influence on blood cells. What about the work of Minot? He admitted that this was valuable and he advised liver treatment. But osteopathic treatment influenced the liver and helped. Challenged on the last claim, he could produce no evidence. He never treated cancer by manipulation. Why should not candidates qualify as physicians and then study osteopathy in a postgraduate course? He answered that it was unfair to ask them to spend

seven or eight years on their course. In all his cases of diphtheria he had found subdislocations of the spine.

CROSS-EXAMINATION BY LORD DAWSON

Dr Macdonald was then cross-examined by Lord Dawson, president of the Royal College of Physicians. Could he produce scientific evidence under the headings (1) x-ray methods, (2) a recorded series of cases, (3) necropsies as to the osteopathic treatment of epilepsy? He answered that the evidence was to be had, but when asked whether absolutely and systematically arranged he said "Not as I would lay it out if I were going to a medical meeting". After further questions, Lord Dawson said "Do you know what makes me despair of this inquiry? I cannot nail a single thing to the counter. I have done my level best to look at this with complete impartiality. Unless we can get well defined answers to certain questions this inquiry is futile. I have never been mixed up with an inquiry where it was so difficult to get an answer. You have said that in diphtheria you would use serum. Yes. In syphilis would you use mercury? Yes. Before asking the nation to change its whole policy, osteopaths must prove their case". Dr Macdonald then said "This is the first time that any responsible person in this country has ever been willing to investigate osteopathy. We have our proof ready. We are prepared to take our stand on several bulletins I have produced at this inquiry, with two or three articles out of the *Journal of the American Osteopathic Association*. The medical profession has never investigated osteopathy". To this the reply can be made that whatever the alleged evidence—and a case of some kind can be made out for almost any treatment—it is manifestly not sufficient to enable Dr Macdonald or the osteopath who preceded him to give satisfactory answers to the crucial questions put to them in cross examination.

The inquiry continues.

The Extermination of Imbeciles

At the Eugenics Society, Dr Frederick Grundy, health officer, gave the results of a mental survey of the school population in Northeast Suffolk. In a school population of 6,600 he found 165 defectives 135 feeble-minded, 23 imbeciles and 7 idiots. Half the children certified as feeble-minded in the educational sense would not be classed as feeble-minded when they reached adult years in rural areas. Feeble-mindedness was greatest in the areas more isolated geographically, where migration of the fittest caused increasing concentration of the poorer stocks. Parentage by the deficient should be prevented by compulsory or voluntary sterilization. They might be kept in colonies where they could be provided with what occupation they were capable of. As to imbeciles, there was only one thing to do with them—to exterminate them as they arose. He made this suggestion purely on humanitarian grounds. It was not fair to the low-grade defectives themselves to allow them to survive.

Murder by Injecting Plague Bacilli

A crime is reported from India of a kind so far unknown in Great Britain—murder by injecting disease germs. The case, which has been before the Indian courts since December 1932, has ended in two death sentences. Amarendra Chandra Pande an Indian aged 21, had a large interest in an ancestral estate. A first attempt to kill him was made by his step-brother, Benoyendra Chandra Pande who presented him with a pair of new spectacles on the bridge of which was smeared a culture of plague bacilli. Amarendra returned them, as they did not fit. But Benoyendra said this was nonsense, placed them on his brother's nose and forced the bridge down so firmly that Amarendra said "It felt as if a vein in my head had burst". A few days later he became ill with lock-jaw and, though the illness was serious, he recovered. It seemed then, said the prosecution that the conspirators considered that the

virus was not powerful or fresh enough. There was only one place in India at which an active culture of plague bacilli could be obtained—the Haffkine Institute, Bombay. Benoyendra went there but found that only a physician could obtain a culture. Dr. Taranath Bhattacharya, a research worker in Calcutta and a brother-in-law of Benoyendra, then came on the scene. He stated that he was experimenting with a cure for bubonic plague and obtained a culture. The scene then shifted to the crowded railway station of Howrah, Calcutta, on a day selected when Amarendra was going away. At the trial a witness stated that Amarendra told him in the railway carriage that when he was in front of the ticket office a dark complexioned man clad in white, brushed past him and he felt a prick. He traveled as far as Pakaur, a distance of 150 miles but returned on the next day as he felt ill. Some eminent physicians saw him in consultation and he died after a few days illness and was cremated. The report does not state what diagnosis, if any, was made. Benoyendra was found guilty of plotting his death to obtain his estate and Dr. Bhattacharya of conspiring to commit murder. Both were sentenced to death. It is to be noted that it was not actually proved that Amarendra died from plague though all the circumstances point to this as well as to the conspiracy to murder him.

The Objectives of Eugenics

Professor Paucot, at the dedication exercises of the new Institute of Social Medicine at Lille, stated that the science of eugenics should form a part of the curriculum of such an institution. The program of this institute includes not only research that is entirely of historical or scientific character but also a study of how one can improve the human race, such as the problems relating to heredity, alcoholism, syphilis, movement of population and the management of delinquency. It is essential that the physicians of France should interest themselves in the theoretical discussions concerning eugenics because some day they may be called on to give their opinion on the methods of application of certain of its principles. The cooperation of medical men is indispensable to the enforcement of laws that will be passed when some of the modern principles of eugenics are to be enforced, as has already been the case in other countries. The means employed thus far to improve the human race can be placed under three heads or groups:

The first method which can be termed negative eugenics aims to sterilize those who have hereditary or physical defects, as has been carried out in the United States and more recently in Germany. This is what Couveaire terms destructive eugenics. A less severe barrier is to place a veto on the marriage of certain individuals as the result of an obligatory prenuptial examination. Under the same heading belongs the birth control movement which furnishes contraceptive remedies to those who live in physical or moral misery. This method, however, as experience teaches, is more likely to decrease the birth rate as a whole than to prevent the birth of the undesirable. At the third International Eugenics Congress Sir Bernard Mallet stated that birth control had a 'dysgenic repercussion' by decreasing the fecundity of those in the better social stratum while it leaves practically unchanged the fecundity of individuals not qualified to reproduce. The practical application of sterilization and interdiction of marriage have encountered almost unsurmountable obstacles. As Dr. Papilaut has said even if one can accept theoretically the idea itself of hereditary transmission to offspring of the taints of those unfit for modern society, one is convinced that the laws of inheritance of each normal or pathologic characteristic

especially in the intellectual sphere differ sensibly from the laws of anatomic heredity. The laws of heredity in the intellectual sphere lack precision and are as yet known so little that one cannot put theories into practice. Such is the opinion of the majority of those best informed on the subject of eugenics in France. It differs from that held in the United States, the Scandinavian countries, and more recently in Germany. Abortion is today regarded as a legal eugenic measure in Russia.

The second group is termed "positive eugenics." Those who favor this method believe that it is easier to apply legal methods than to suppress or reduce the fecundity of the unfit; that is, to put into practice "negative eugenics" as opposed to "positive eugenics," which favors the birth of individuals who are well endowed physically and mentally. The idea of positive eugenics is a rational one and would be of unquestionable social utility if it could be applied. It is a direct attack on human liberty and its results are no less certain than those of "negative eugenics." The idea of "positive eugenics" is to create a superior human race just as one tries to breed a similar race of superior animals.

A third formula is that of "corrective eugenics," the possibilities of which are more acceptable. This is being applied in France in the form of "prenatal puericulture" which aims in a modest manner, without the use of force but simply by self-discipline to secure all that is best from the human assets at its disposal. Prenatal consultations, centers of puericulture, homes for mothers, antisiphilic dispensaries and annexes to maternity hospitals have all greatly lessened the percentage of abortions and deaths of mothers and infants. It is necessary to extend this campaign of vulgarization of the laws of hygiene to the prospective fathers as well as to the mothers. Professor Pinard has proposed a law making a health certificate necessary before marriage licenses can be issued. French eugenicists do not believe, however, that such a law will prevent any more unfit human beings to be born. Professor Paucot is an ardent supporter of the idea of vulgarization of the laws of hygiene and believes that it will result in attracting the attention of those who have hereditary taints, especially syphilis, to the danger of having unfit offspring. Such a method of 'corrective eugenics' does not interfere with personal liberty but aims by education to improve the individual conditions of procreation. This will be the task to which the medicosocial department of natality of the new Institute of Social Medicine at Lille will devote itself.

New Journal on Immunology

The first issue of the *Revue d'immunologie* appeared in January. The editors, all well known in the field of immunology, are Profs. Robert Debre, G. Ramon and Pasteur Vallery Radot, the grandson of Louis Pasteur. In the introduction, Prof. Jules Bordet stated that such a journal fills a long felt want for the publication not only of reviews of articles in this special field, which appear in foreign journals, but to enable the large number of papers emanating from French sources and which are widely scattered in various journals to be subjected to a critical evaluation before being published in a single special journal. In the first issue are papers by Charles Nicolle, an internationally known bacteriologist, on immunity and immunization against typhus exanthematicus, one by Ramon on antidiphtheria and antitetanic vaccination by means of specific anatoxins, one by Pasteur Vallery Radot on the parallelism between provoked and spontaneous anaphylaxis, an article on the method of action of the immunity created by diphtheria anatoxin, by Ramon Debre and See, and one by Jean Hamburger on the problem of allergic migraines. The first issue reflects the great advance in research in the field of immunology made by French immunologists.

The Results of the Publicity Campaign on Cancer

Concerning the value or the danger of a publicity campaign on cancer the views of experts differ widely. It is therefore perhaps of interest to report on some recent utterances that have been published in various parts of the German Reich. At the session of the Vereinigung nordwestdeutscher Chirurgen, Klingen, of the surgical clinic of the University of Greifswald (Pomerania), spoke on the subject. In this clinic, observations on more than 2,300 cancer patients have been made over a period of twenty-three years, with fairly detailed information on each individual case. Attempts to enlighten the people on cancer problems by means of distributed leaflets and lectures have not proved successful in this province. Better results were secured through careful instruction of the care-taking personnel and the workers in the large leagues, including the official welfare workers. The greatest success has been achieved by a thorough training of the students and by the organization of continuation courses for physicians. To these measures is due the fact that in recent years cancer patients have been coming earlier for operation. The value of roentgen examinations for the diagnosis is great but must not be over-estimated. Bioptic excisions should be made only in very obscure cases and only by the surgeon. No harm is done by such excisions, in the opinion of Professor Anschütz, of Kiel.

The experiences in other regions appear to be different. In Berlin, Hintze, roentgenologist in the surgical clinic in charge of Bier, announced recently that the knowledge of cancer in the medical profession and also among the people had improved to such an extent that four fifths of the cases of cancer of the breast had been found operable by this clinic.

The reports from Baden, on the other hand are less favorable. In the surgical clinic of the University of Freiburg, Dr. Karitzky studied the results of cancer publicity in Baden. He examined the records of about 1,800 patients who had been operated on for malignant growths during the period 1920-1933. He reached the conclusion that the campaign for the enlightenment of the people on cancer problems (with the exception of skin cancers) had had little influence on the usual delay of patients before consulting a physician or on the operability of the tumors. The benefits that patients derive from such a campaign are exceedingly small, while in some instances, owing to the unnecessary fear aroused, great damage is done. In view of these observations, the Freiburg clinic refuses to participate in any publicity campaign especially (which constitutes a weighty argument) so long as no reasonably sure cure is available.

Finally, Hamburg has published its observations on an interesting series of cases. In Hamburg the notification of tumor patients is not compulsory. Compulsory notification is regarded as impracticable, so long as a rapid and sure diagnosis of the early cases—the beginning stage—is impossible. Publicity campaigns, or attempts to enlighten the people on cancer by means of distributed leaflets, placards, and the like are not in favor in Hamburg. It is held that the daily papers contain enough such information. There is, however, a sort of welfare center for cancer patients. There are three welfare aid workers who support the activities of the physicians by general control measures by constant contact with the cancer patients, and by keeping a central file of the record cards of all patients. Patients belonging to the insured class (that is, members of the health insurance associations) receive adequate care so that for them no special institutes for early diagnosis are needed. They are needed, however, for the noninsured that is, for certain persons of small means, and also for the well to do

class. These institutes, together with their equipment, should be available for all physicians. Some interesting facts are deducible from the Hamburg statistics. Compared with the total number of deaths, 26 per cent of the male and 25.5 of the female cancer patients had had no contacts with the welfare aid service. In the opinion of the head municipal physician, a remedying of this defect ought to be possible if a closer cooperation of all physicians could be secured. On the other hand, the number of patients cared for in 1934 increased by 1,000 which was doubtless due to the greater energy developed and not necessarily to any increase in the number of cancer cases. Among these patients there were three times as many women as men. For example, in one week of December 1934 the total number of patients being cared for by the welfare aid service was 5,257 (1,384 men and 3,873 women). Likewise the combating of quackery in Hamburg has achieved considerable success. The authorities have put an end to the fraud perpetrated in the form of alleged radium jars. Publicity lectures by laymen are no longer permitted. One unethical radiologic institute has been closed. The advertising pages of all Hamburg daily papers are, and have been for many years, strictly censored.

The Crusade Against the Improper Sale of Medicines

For many years a campaign has been carried on against the improper advertising and sale of medicines, but with the advent of the new regime the crusade has been pursued with doubled energy. A previous letter told of the introduction of new police measures dealing with the subject in Prussia (THE JOURNAL, Aug. 12, 1933, p. 536). Two recent occurrences will illustrate the vigor with which the laws are being enforced. In Munich, the three partners of a firm were arrested by reason of conduct bringing damage to the people" and some of them were taken to a concentration camp. They had pushed the sale of alleged remedies that, in point of fact, had no practical value, and in their advertisements they had made improper use of statements made by certain federal ministers. It was found that a "bath improver" sold by them consisted almost exclusively of turpentine and soft soap. The firm charged 22 marks for a package of the article, whereas the cost of production was about 2.20 marks.

Interest attaches also to a decision of a superior court. A daily paper had warned its readers, composed to a great extent of farmers inexperienced in such matters against the purchase of expensive remedies that are at least of doubtful efficacy if not absolutely worthless. The articles aimed at more particularly were "radium pillows" and "ultra-active radium salts." The firm exploiting the articles brought suit against the newspaper containing the warning. The court rendered a decision adverse to the plaintiff, which was based not only on the opinions of the experts summoned by the court but also on the listed duties that the new laws impose on editors, for recent legislation requires editors to place movements in the foreground that are designed to promote public welfare. Collaboration in the production of the intellectual contents of the newspapers is regarded as a public task. Hence the newspaper acted in a manner to preserve justified interests, even though the warning may have proved harmful to the firm concerned.

Medical Practice Pertaining to Accidents

Medicine pertaining to accidents is gaining in importance and is developing more and more into a complicated field of activity. Evidence of this fact was furnished by the session of the Deutsche Gesellschaft für Unfallheilkunde, which was held recently in Würzburg and was well attended. The steady increase of accidents has brought medicine pertaining to accidents also from the medicolegal point of view, into the fore-

ground. As the chairman, Prof F König, surgeon, of Würzburg, pointed out, the question of compulsory acceptance of a needed operation appears to be sufficiently clarified to justify the expectation that within a reasonable time new legislation on the subject will be forthcoming. In hospitals and in university clinics the creation of special departments for the handling of accidents and the extension of existing special equipment furnish evidence of a desire to take account of the increasing need of better facilities for the care of persons injured in accidents. By the organization of special courses the faculties of medicine have met the demands for special training in the handling of accidents, as expressed by the oncoming generation of physicians. Professor König brought out further that, if surgeons attached to the university clinics should develop a special interest in medicine pertaining to accidents and should desire to give up general surgery and to enter the special field of "accident surgery," it must be expected that these physicians, who voluntarily renounce every other surgical activity in the interest of health insurance policyholders (Krankenkassen and the like), will find the way prepared for the creation of an independent hospital for accidents.

CEREBRAL AND CRANIAL INJURIES

The first main topic dealt with was "Cerebral and Cranial Injuries." Speaking from the neurologic point of view, Heyde of Würzburg brought out that extensive cerebral injuries may cause relatively slight disturbances, whereas cerebral injuries of slight extent may cause serious disturbances. Not infrequently, in cases that during the lifetime of the patient, could not be correctly judged, the actual connections are clarified at necropsy by the pathologic examination of the brain, hence in all cases of cerebral injury an anatomic examination of the brain should be demanded as a routine principle. In open cranial injuries, owing to an increase of the internal cerebral pressure, a primary cerebral prolapse may occur, with a menace of meningitis and cerebral infection. Further on there is danger of a late secondary infection, late abscess and traumatic epilepsy. Provided an operation within from six to twelve hours is possible, Wanke of Kiel pointed out that, in open cranial injuries, only closed treatment is indicated together with scrupulous removal of contaminated tissues and primary closure of the wound. The results are much better than with the half-open, or with the open wound treatment, with the many possibilities of complications. Of the patients given closed treatment only 6 per cent developed a traumatic epilepsy, as compared with 12 per cent receiving open treatment.

Tonnies of Würzburg emphasized that intracranial hemorrhages may require a surgical intervention long after the accident. He warned against the customary plugging treatment in late epilepsy. Importance attaches to the loosening of the scar, which should be cut out; then the edges of the dura are sutured to the periosteum, without the introduction of any plastic equivalent to remedy the defect.

The question was discussed as to whether on the basis of previous experiences it was correct to insist on the patient remaining six weeks in bed in the event of concussion of the brain. Sommer of Dortmund had found that in many cases bed rest for from eight to ten days will suffice, but he emphasized that one should insist on the patient remaining at least three weeks in the hospital.

THE IRRITABLE KNEE

The second main topic on the program was "The Irritable Knee." The speakers were Burkle de la Camp of Bochum, Andreesen of Bochum, and Gebhardt of Hohenlychen. It should be borne in mind that capsular changes, injuries of the ligamentary apparatus or the menisci, pathologic changes in the articular cartilage and retention of wedged-in tissues—

alone or in combination—may cause disturbances in the function of the knee joint, which must be taken into account in examining an irritable knee joint. The roentgenogram does not always aid in clarifying the diagnosis. Especial attention should be given to the knee joints that are subjected to constant occupational injuries, for example, in miners. Anatomic-pathologic examination of such joints in miners will clarify in part the chronic irritation symptoms with their sequels. One may find evidence of transitions between erosion manifestations in the knee joint and constant occupational injuries.

BELGIUM

(From Our Regular Correspondent)

Feb 19, 1935

The Advertising of Pharmaceuticals

At the third congress of the Federation de la presse medicale latine, Professor Gunsburg of Antwerp and Dr Watru of Brussels discussed the relations of the medical press and the advertisers of pharmaceuticals. They took up (1) the possible advantages and disadvantages of advertising in medical journals, (2) advantages of advertising for the various interests, (3) dangers of medical advertising, and (4) amicable relations between the medical press and the advertisers, and professional ethics as affecting physicians and advertisers. The speakers concluded that the chief role of advertising in the medical journals is to make known in a scientific manner the new things in therapeutics and instrumentation, and to create a feeling of confidence between the manufacturer of pharmaceuticals and the medical profession. The absolute independence of the editorial department must be preserved, and the greatest frankness must constitute the basis of advertising agreements and contracts. Rules affecting the ethical relations of the medical press and advertisers are to be drawn up by the Federation de la presse medicale latine, which will serve as a basis for the settlement of any controversies that may arise.

Blood Transfusion Service

The central Red Cross blood transfusion service has begun to function. The purpose of the new service is to place donors previously examined and controlled in a systematic manner at the disposal of hospitals, clinics and the medical profession in general. In response to a day or night call this central service will send donors to any place indicated. The donors all carry an identification card which shows also the blood group (the Moss classification) to which they belong. The identification cards are inspected every three months by the physician in charge of the "technical committee." The physician who performs the transfusion must indicate on the identification card the date and the place of the transfusion and the quantity of blood withdrawn. If need be, the service will supply physicians with the instruments required for transfusion. On request of families or of the attending physician, it will give the names of physicians especially qualified to perform a transfusion and in a position to respond promptly to a summons. The organization of such a service has necessitated the creation of a strict examination and control. Thus, donors agree to present themselves every three months at the headquarters of the central service to have the identification card visaed. They agree to report also any disease that they may contract, or any circumstance that would prevent them either for the time being or indefinitely from responding to a call.

The Centenary of the Royal Society of Medicine

The centenary of the Royal Society of Medicine of Ghent was celebrated with éclat. More than 300 physicians from France and from all parts of Belgium responded to the summons of the committee, desiring to show their interest in the movement by their presence. On this occasion Mr Bersaques

secretary of the society, gave a historical account of the work of the society, the motto of which is "science and philanthropy" which has been exemplified by the great service rendered in the development of medical science, by the amicable collaboration with the university, and by the comfort it has given the poorer classes by creating free consultation centers for the indigent

The Centenary of the University of Brussels

The ceremonies in celebration of the hundredth anniversary of the founding of the University of Brussels were honored by the attendance of the king. The minister Paul Hymans, chairman of the council on administration, gave a historical account of the work of the University of Belgium from the time when Theodore Verhaegen demanded its creation down to the wonderful developments that all can witness today. During the course of his address the eminent minister took frequent occasion to pay homage to the physicians Rommelaere Heger, Brachet Depage and many other professors of the Faculty of Medicine in addition to the services that they rendered in training by their instruction scientists and practitioners, or in advancing the cause of science by their researches, consecrated themselves devotedly to improving the university as a whole. A series of lectures was delivered by the professors of the university, special mention being made of the address of Professor Dustin on "Medicine and the Liberal Type of Examination." The speaker considered in turn the past twenty-five years of the Faculty of Medicine of the University of Brussels, the progress realized in medicine during the past century, and the history of medicine from Hippocrates down to the present.

After recalling the marvelous institutes erected twenty-five years ago, through the initiative of Paul Heger and the generosity of the Solvays, the Warocquus and the Jamars—institutes that the unceasing progress of science and the needs of modern research, demanding the proximity of an active clinic and laboratory, have caused to become in a measure obsolete after so brief a time, the speaker observed with just pride and satisfaction, that the modern institutes and the Hospital St. Pierre (about ready to open) were erected, with the aid of the Rockefeller Foundation, at Brussels for good reasons. It was owing to the reputation of its investigators and the spirit that animates them, as expressed in the persons of Depage, Bordet and Brachet, among others, that the University of Brussels secured this marvelous gift. Under the influence of Laennec, Pasteur, Lister, Virchow, Roentgen and of Bordet, Gengou and Ehrlich, medical science during the past century, has undergone a rapid and marvelous development. Other epochs, to be sure, have had similar medical apogees: Hippocrates, Aristotle, Galen, Vesalius, Morgagni and Bichat—to cite only a few names—played an important part in holding aloft the torch of science, but during those distant epochs the light of knowledge pierced with difficulty the density of ignorance. Recent acquisitions are introduced more easily and inure more rapidly to the benefit of the masses than did the first forward steps owing to the unwillingness of an ignorant and superstitious people to accept them. While it is true that, at the present time men of science understand one another very well and the objects of their researches, irrespective of the milieu, the speaker held that the shackles from which, during the course of centuries, scientific research and particularly medicine have freed them might bind them again some time in the future. The art and science of medicine are evolving constantly, they will not be tomorrow what they are today. They may and they should become rationalized, they should not be made servile or be functionalized.

Science is a vivacious plant and demands a liberal space for its normal development. It cannot be domesticated. Those who wish to cultivate it can do so only under full and complete liberty.

Child Mortality

At the Ecole de puériculture, and in the presence of her majesty the queen, Dr. Lust delivered recently an interesting introductory lecture. The following excerpts will demonstrate the results secured by the various societies established in Belgium for the protection of children. In 1919 was founded the Oeuvre nationale de l'enfance, an official organization generously subsidized by the public authorities. Its purpose is to coordinate, promote and stimulate private initiative. It inspects and controls the activities of the societies, subsidizes them if need arises and carries on a wide publicity campaign with a view to making better known the essential ideas of child hygiene and the advantages of breast feeding by the mother. It supervises through the physicians and the nurses of the consultation centers for nursing mothers, children who are being guarded or who are being nursed outside the home. Its social service considers requests for aid in favor of children. In 1933 the Oeuvre nationale de l'enfance controlled 1,174 consultation centers for nursing mothers in 669 communes, 225 prenatal consultation centers, six homes for mothers or expectant mothers, sixty-four day nurseries and nursing centers, and thirty-three vacation colonies for weakly children. All these societies owe their creation to private initiative but are inspected and supervised by the Oeuvre nationale. The Oeuvre nationale de l'enfance directs personally seven colonies for weakly and convalescent children, two institutions for the reeducation of abnormal children and a small model nursing center. This enumeration evidences the activity of this organization and the great progress that is being made in Belgium in the crusade against child mortality. Not only has child mortality been diminished, but the daily clinical experience goes to show that the nurslings of 1934 are better cared for and are more robust than their parents were at the same age.

Many countries have reduced child mortality to a greater extent than Belgium. Some twenty countries lose proportionately fewer nurslings than this country. Whereas in New Zealand only thirty-two infants per thousand die under 1 year of age, there are fifty-seven in Sweden and ninety-two in Belgium. There is another means that might be employed to save many infants from an untimely death. Among the factors that influence morbidity and mortality among young children the author mentions unhealthful and crowded dwellings, inadequate aid to weakly and sickly infants, the separation of mother and child, and the inadequate number of competent aids in the societies for the protection of children.

Marriages

DANIEL R. WILSON, Kansas City, Kan., to Miss Ethel Lorene Matts of Topeka at Kansas City, Mo., January 16.

JOSEPH LAYMAN GUFFY to Miss Emily Denson Payne, both of Birmingham, Ala., February 16.

ALBERT JOHN BRANDT, Youngstown, Ohio, to Miss Elizabeth Bell of New Castle, Pa., March 2.

CHARLES N. MANLEY, Cincinnati, to Miss Kathleen Kirk of Memphis, Tenn., February 9.

EDWARD M. LIPSETT, San Francisco, to Miss Sonya Saylin at Reno, Nev., February 17.

BENJAMIN E. URDAN to Miss Marian Daneman, both of Milwaukee, February 7.

PAUL R. ROLLINS, Seattle, to Miss Martha Harlan of Farmington, Mo., January 1.

CHARLES A. BAYER to Miss Mildred Mason, both of Toledo, Ohio, February 19.

RAYMOND L. HILSINGER to Miss Angelese Hays, both of Cincinnati, recently.

JOHN P. McVAY to Miss Josephine Mears, both of Seattle, April 4.

Deaths

William Fowke Ravenel Phillips ♂ Washington, D. C., Columbian University Medical Department, Washington, 1890, professor of anatomy, Georgetown University School of Medicine, professor of hygiene, George Washington University, 1891-1892 and 1895-1909, dean of the department of medicine, 1904-1909, and professor of practical anatomy, 1905-1909, professor of anatomy, University of Alabama School of Medicine, Mobile, 1911-1915, and the Medical College of South Carolina, Charleston, 1915-1933, medical climatologist for the U. S. Weather Bureau, 1895-1904, and librarian, 1898-1904, member, in 1902 vice president and in 1905 president of the American Clinical and Climatological Association, member of the South Carolina Medical Association, secretary of the Anatomical Board of the District of Columbia, 1902-1911 fellow of the Federation of State Medical Boards of the United States, aged 71, died, February 16, in the Georgetown University Hospital, of pneumonia.

Douglas Fox Wood, Minneapolis, McGill University Faculty of Medicine, Montreal, Que., Canada, 1900, member of the Minnesota State Medical Association, and the American Academy of Ophthalmology and Oto-Laryngology, fellow of the American College of Surgeons, formerly on the staffs of the Northwestern, Abbott, and Swedish hospitals, aged 60, died, February 9, in St. Petersburg, Fla., of coronary occlusion.

Lester Floyd Cleland, Lisbon, N. Y., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1912, member of the Medical Society of the State of New York, served during the World War, bank president, health officer of Lisbon since 1916 for sixteen years president of the board of education, for six years district coroner, aged 55, died, February 19, of pulmonary embolism.

James Vance McGougan, Fayetteville, N. C., University of Maryland School of Medicine, Baltimore 1893, past president of the Medical Society of the State of North Carolina formerly member of the state legislature, county coroner at one time trustee of the University of North Carolina School of Medicine, Chapel Hill, aged 64, died, March 13, in Lumber Bridge, of cerebral hemorrhage.

Jonathan B. Vail, Lima, Ohio, Medical College of Ohio, Cincinnati, 1871, member of the Ohio State Medical Association, Civil War veteran, at one time mayor of Kalida, formerly city health officer and member of the school board, trustee of Miami University, Oxford, since 1911, aged 90, on the staff of the Memorial Hospital, where he died February 14, of senility.

George Louis Vogel ♂ Boston, Harvard University Medical School, Boston 1900, served during the World War, member of the New England Otolaryngological and Laryngological Society for many years on the staff of the Boston City Hospital, aged 61, died, March 12, in the Trumbull Hospital, Brookline, of streptococcal septicemia the result of osteomyelitis.

Charles Clyde McLean ♂ Dayton, Ohio, Medical College of Ohio, Cincinnati, 1895, member of the Associated Anesthetists of the United States and Canada, past president and secretary of the Montgomery County Medical Society, aged 62, on the staff of St. Elizabeth's Hospital, where he died, March 12, of cerebral hemorrhage.

Edward William Whitney ♂ Northampton, Mass., Harvard University Medical School, Boston, 1903, member of the American Psychiatric Association and the New England Society of Psychiatry, medical superintendent of the Northampton State Hospital, aged 55, died, February 16, of cerebral embolism and chronic endocarditis.

William Thatcher Baker, Dallas, Texas, Atlanta (Ga.) Medical College, 1895, past president of the Dallas County Medical Society and the Ellis County Medical Society, on the staff of the Parkland Hospital, served on the examining board during the World War, aged 71, died, February 19, of Hodgkin's disease.

Benjamin Chester Everall, San Antonio, Texas, Drake University College of Medicine, Des Moines, Iowa, 1907, fellow of the American College of Surgeons, formerly on the staffs of the Allen Memorial, Presbyterian and St. Francis hospitals, Waterloo, Iowa, aged 53, died recently, of amoebic dysentery.

Ralph Clinton Larrabee ♂ Boston, Harvard University Medical School, Boston, 1897, member of the New England Pediatric Society, formerly associate professor of clinical medicine, Tufts College Medical School, on the staff of the Boston City Hospital, aged 64, died suddenly March 9.

John Marshall Barnwell, Florence, S. C., Medical College of the State of South Carolina, Charleston, 1913, served during the World War, on the staff of the Saunders Memorial Hospital, aged 43, died, February 24, in St. Joseph's Sanatorium, Asheville, N. C., of pulmonary tuberculosis.

Noble William Miller, Chicago, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906, served during the World War, aged 52, died, March 23, in the Veterans' Administration Facility, Hines, of hemorrhage, the result of a peptic ulcer.

Edward Lawrence Peirson, Salem, Mass., Harvard University Medical School, Boston, 1888, member of the Massachusetts Medical Society, for many years on the staff of the Salem Hospital, aged 72, died, January 18, of hypertension, heart disease and chronic arthritis.

Isabel Taylor Macmillan, New York, Woman's Medical College, Chicago 1889, member of the Medical Society of the State of New York, on the courtesy staff of the New York Infirmary for Women and Children, aged 72, died, March 26, of arteriosclerosis.

Augustine Joseph Molloy, Bayonne, N. J., Columbia University College of Physicians and Surgeons, New York, 1896, Dartmouth Medical School, Hanover, N. H., 1896, on the staff of the Bayonne Hospital, aged 62, died, February 23, of endocarditis.

James Saundry Trehwella ♂ Montebello, Calif., Northwestern University Medical School, Chicago, 1905, member of the Associated Anesthetists of the United States and Canada, served during the World War, aged 64, died, February 11, of heart disease.

Thomas Byrne Walsh, Syracuse, N. Y., Syracuse University College of Medicine, 1919, member of the Medical Society of the State of New York, aged 44, died, February 9, in the Syracuse Memorial Hospital, of coronary thrombosis and pericarditis.

John R. McCurdy ♂ Pittsburgh, University of Pennsylvania Department of Medicine, Philadelphia 1900, member of the Associated Anesthetists of the United States and Canada, aged 60, died, March 9, of cerebral hemorrhage and arteriosclerosis.

John Archibald, Cohoes, N. Y., Albany Medical College, 1888, member of the Medical Society of the State of New York, formerly mayor and health officer of Cohoes, on the staff of the Cohoes Hospital, aged 74, died, March 4, of cerebral hemorrhage.

William S. Powell ♂ Defiance, Ohio, Jefferson Medical College of Philadelphia, 1874, past president of Defiance County Medical Society, formerly on the staff of the Defiance County Hospital, aged 84, died, March 3, of fracture of the hip.

George Washington Banks, Shepherdstown, W. Va., University of Maryland School of Medicine, Baltimore 1897, on the staff of the King's Daughters' Hospital, Martinsburg, aged 79, died, February 26, of cirrhosis of the liver.

Charlotte Belle MacArthur, Willard, N. Y., Northwestern University Woman's Medical School, Chicago, 1897, for many years on the staff of the Willard State Hospital, aged 66, died, February 19, of carcinoma of the lung.

James Estelle Dunlap, Schlatter, Miss., Memphis (Tenn.) Hospital Medical College, 1912, member of the Mississippi State Medical Association, served during the World War, aged 47, died, March 12, of heart disease.

John Lewis Peppers ♂ Webster City, Iowa, Keokuk Medical College, College of Physicians and Surgeons, 1902, past president of the Twin Lakes District Medical Society, aged 64, died, January 20, of heart disease.

Myron C. Hawley, Randolph, N. Y., University of Buffalo School of Medicine, 1881, member of the Medical Society of the State of New York, aged 78, died, February 24, of diabetes mellitus and cerebral hemorrhage.

Martin Joseph Cooney, New York, Georgetown University School of Medicine, Washington, D. C., 1906, served during the World War, aged 55, died, March 6, in the Bellevue Hospital, of skull fracture.

Benjamin Edwin Moody, Hutchinson, Kan., Missouri Medical College, St. Louis, 1884, formerly on the staff of the Kansas State Hospital, Larned, aged 75, died suddenly February 16, of heart disease.

Ernest Spencer, Bel Alton, Md., University of Maryland School of Medicine, Baltimore, 1892, member of the Medical and Surgical Faculty of Maryland, aged 65, died, March 12, of chronic myocarditis.

Frank Evans Christopher, Bolinger, Ala. Louisville (Ky.) Medical College, 1894, member of the Medical Association of the State of Alabama, aged 68, died recently, as the result of an automobile accident

Charles A Borey @ New Orleans Tulane University of Louisiana Medical Department, New Orleans 1895 aged 62 died February 27, in the Hotel Dieu Hospital of adenocarcinoma of the thyroid

Frank J Brown, Los Angeles George Washington University School of Medicine Washington D C, 1908 aged 59, died, March 6, in Orlando, Fla., of arteriosclerosis and coronary sclerosis

John Benjamin Thielen, New York, University of Michigan Department of Medicine and Surgery, Ann Arbor 1897 aged 64, died February 4 of cerebral hemorrhage and pulmonary edema

Robert E McDade, Chicago Jenner Medical College Chicago 1917 member of the Illinois State Medical Society, aged 45 died March 22, of hemorrhage following a cholecystectomy

Lynn H Case, Santa Monica, Calif. Hahnemann Hospital College of San Francisco 1900, aged 57 on the staff of the Wilshire Hospital where he died, February 28 of acute nephritis

Charles Fletcher Souder, Red Bank, N J. Hahnemann Medical College and Hospital of Philadelphia, 1892 aged 67 died February 1 of chronic myocarditis and a ray burns of the legs

John E Standifer, Elk City, Okla. (licensed in Oklahoma under the Act of 1908), member of the Oklahoma State Medical Association, aged 68 died recently of hydronephrosis and pyelitis

Edwin A Simonds, Carthage N Y, Hahnemann Medical College and Hospital, Chicago 1884, for many years health officer of Carthage, aged 75, died, March 2, of angina pectoris

Martin E Rudolph, Aurora Ill. Rush Medical College Chicago 1928, member of the Illinois State Medical Society, aged 32 died, March 29 of suffocation the result of a fire

Robert George Anderson, Elyria, Ohio Trinity Medical College, Toronto Ont., Canada, 1895, on the staff of the Elyria Memorial Hospital, aged 68, died, March 3, of heart disease

William Alvin Denson, Chilton, Texas (registered by Texas State Board of Medical Examiners under the Act of 1907), aged 69, died, January 3, of angina pectoris

Benno Johann Anton Nachtigall @ Cleveland Medizinische Fakultät der Universität Leipzig Saxony, Germany, 1893 aged 73, died, February 20, of coronary thrombosis

Edith Leavitt Clarke, Winter Park, Fla., Boston University School of Medicine 1885, aged 75, died, March 9, in the Florida Sanitarium, Orlando, of pneumonia

Porter Douglas Blackburn @ St. Louis Washington University School of Medicine, St. Louis 1910, aged 52 died March 12, of hypertension and nephritis

Dennis Francis O'Connor, Elkton, S D., University of Minnesota Medical School, Minneapolis, 1890 aged 70 died, February 12, of dilatation of the heart.

Henry W Himmelberger, Reifton, Pa. University of Pennsylvania Department of Medicine, Philadelphia, 1869, aged 89 died, February 27, of senility

Hugh Park, Niagara Falls, Ont., Canada University of Toronto Faculty of Medicine, 1875 aged 82, died February 27, of acute suppurative meningitis

William Pearson, Fall River, Mass. (licensed in Massachusetts in 1904), aged 82, died, January 19, of cerebral hemorrhage and arteriosclerosis

Russell Ross Burt, Los Angeles Rush Medical College Chicago, 1903, aged 59, died January 28 in the Hollywood Hospital, of myocarditis

Robert L Sears, Whitewright, Texas, University of Louisville (Ky.) Medical Department, 1891, aged 66, died, February 11, of pneumonia

Henry Nickey Rice, Covina Calif. Rush Medical College, Chicago, 1886, aged 91 died, January 22 of bronchopneumonia

Lewis Morris, New York, Bellevue Hospital Medical College, New York, 1890, aged 74 died, January 10 of lobar pneumonia

James H Mattox, Hemphill Texas (licensed in Texas in 1908), aged 76, died, March 9, of diabetes mellitus

David L Rollins, Bog Springs, Ark. (licensed in Arkansas in 1903), aged 70, died recently of heart disease

Bureau of Investigation

GERTRUDE NOVA "OBESITY CURE"

Another Dangerous Nostrum of the "Get-Thin-Quick" Type

Gertrude Nova, Inc., sells an alleged obesity cure from Denver, Colo. It appears from material in the files of the Bureau of Investigation that local branches are opened or agents employed operating in different parts of the country. It seems, too, that the stuff is also handled by agents, who sometimes work direct within the limits of their state and sometimes enlist the help of 'beauty parlors' to further the sale of the nostrum.

The Gertrude Nova concern is reported to have been incorporated in 1933 under Colorado laws with an authorized capital of \$50,000. The corporation is said to have taken over the business established individually by Gertrude S. Tenderich in 1928 under the trade name Gertrude Nova. Mrs. Tenderich as president of the concern, has associated with her two men who are respectively vice president and secretary-treasurer. It appears that Mrs. Tenderich in 1933 put on the market a sanitary napkin known as "Tampax," now put out by the Tampax Sales Corporation, of which Mrs. Tenderich is said now to be president and the controlling stockholder.

SLENDER

Loveliness

IS YOURS

If you Reduce this safe, easy way!

Why Be Embarrassed by Fat.

Get Thin and Stay Thin Safely! Surely!

•

No Dieting!

No Exercises!

No Reducing Much and

Slenderness without

Danger!

IMPROVES HEALTH!

Absolutely Harmless!

None of the three persons operating this "obesity cure" is a physician, pharmacist or chemist. Of the two gentlemen who are connected with Mrs. Tenderich one is said to have been employed previously in various lines as a salesman, while the other is a lawyer. This department of THE JOURNAL has repeatedly called attention to the fact that while many "patent medicine" concerns, although exploiting substances of a medical character have no physicians or pharmacists connected with them, they very frequently do have a lawyer occupying an important place in the organization. The reason is presumably that it is much more important, from the nostrum exploiter's point of view, to know how to keep within the letter of the law than it is to know anything about drugs and their actions.

The advertising ballyhoo that accompanies the exploitation of Gertrude Nova's "obesity cure" is to the effect that a noted German physician (name not given), while visiting some friends of one E. G. Kathian, alleged to be a druggist of Trenton, Mo., prescribed an obesity treatment for a member of the Kathian family. The results were alleged to be so marvelous that Mr. Kathian began selling it, and the sale developed to such an extent that he had to conduct the sale of this nostrum as a separate business. More than ten years ago the stuff was sold from Kansas City, Mo., under the somewhat imposing trade name "American Research Institute" and the product was called variously 'Kathian's Scientific Treatment for Obesity' and 'Kathian's Improved Flesh Reducer.' One E. E. Pratt was then in charge of this concern. Later the business seems to have been transferred to Denver, to be operated under the name of Gertrude Nova.

The claims made for the "Gertrude Nova Flesh Reducer" are quite typical of obesity-cure "patent medicines." The overweight are told that it is unnecessary to diet, that they need not exercise, and that the product "improves health" and is "absolutely harmless." These are the claims in the "come-on" literature. When the money has gone over the counter, however, the overweight customer is told that the "enemies of a fat person" are fat meats, sugar, bread, cereals, nuts, butter, bacon, cream, candies, olive oil, rich desserts and pastries. She is told, also, to "try to eat only one starch at a meal" and "to get in a walk every day." Further, the overweight woman is told that she should keep up this diet and continue taking the Nova nostrum continuously for three months, and that "many men and women find that its continued use for a somewhat longer period insures good health and maintenance of normal weight."

In February, 1933, some cursory tests were made of this nostrum in the A M A Chemical Laboratory. At that time the product came in two capsules, one containing a dark yellow substance and the other a light yellow substance. The chemists reported that the drugs in the dark capsule were apparently asafetida and calomel. The contents of the light-colored capsule seemed to be essentially desiccated thyroid, with traces of a powdered leaf drug suggestive of digitalis.

In February, 1933, also, Dr. Pinkham, Secretary-Treasurer of the Board of Medical Examiners of California, sent the Bureau of Investigation a copy of a letter that he had received from Mr. J. W. Davidson, a special agent for the Board and a man who has done much to hamper the activities of quacks in California. A Mrs. Martha Schaefer was at that time the San Francisco distributor of the Gertrude Nova nostrum, known as "Kathan's Original Flesh Reducer." Mr. Davidson stated that it had been claimed that the nostrum was prepared for them by Parke, Davis and Company of Detroit and that it contained no thyroid or other harmful substances.

Recently Mr. Davidson submitted to the Public Health department samples of the Gertrude Nova reducer and also the supplementary nostrum "Novar." Shortly thereafter Dr. J. C. Geiger, Director of Public Health of San Francisco, furnished the Board of Medical Examiners with the laboratory report on the Gertrude Nova "patent medicines" "Reducer" and "Novar." According to this report, the "obesity cure" consisted of two capsules, one gray and one brown, the former responding to tests for thyroid and the latter to tests for laxatives, probably of the cascara and aloes type. The supplementary nostrum Novar was reported to contain phenolphthalein and psyllium seed.

On March 25, 1935 it was reported that Inspector J. A. Bentley of the State Board of Pharmacy of California served an official notice on Martha Schaefer as exploiter of the Gertrude Nova nostrum that this "patent medicine" could no longer be sold unless it was dispensed by a licensed pharmacist under the written instructions of a licensed physician. It would be well if other communities could protect their citizens in a similar way.

From the foregoing, it appears, therefore, that the Gertrude Nova "obesity cure" is another one of the potentially harmful thyroid preparations. It is not surprising, therefore, that an Illinois physician has reported that one of his patients who had been taking this nostrum had "become quite nervous," or that a Kansas physician should have stated that the preparation "produced an acute thyrotoxicosis." A Nebraska physician also wrote that women in that section who had taken the Nova "patent medicine" had noticed "a very marked depression" while a physician in Colorado reported that a patient who had taken a number of the Nova capsules developed a severe colitis with cramping and irritation of the kidneys. Still another physician, in California, reported recently that a woman who had used the Nova preparation for about a month "developed paresthesias, numbness and tingling of the left hand, which grew progressively worse," as well as other untoward effects.

It has been repeatedly emphasized in this department of THE JOURNAL that freak diets and the indiscriminate sale of drugs for the alleged cure of obesity are pernicious and a menace to the public health. Especially dangerous are those anti-fat "patent medicines" that depend mainly, for their action on metabolic stimulants such as thyroid substance or dimetrophenol

Correspondence

GIFT FORM FOR HOSPITALS

To the Editor—Readers of THE JOURNAL may be interested in a simple plan that has been in use at the Sansum Clinic for the past two years not only to interest an increasing number of patients in medical research problems but also to increase the much needed income for this purpose. We call it "Our Birthday Better Health Plan."

During the depression the income from regular sources for the maintenance of research work has been materially reduced but every effort is being made to permit it to be continued. To help maintain this research work we have initiated a simple plan, which is receiving favorable response. We invite our patients who have been aided by the results of medical research

My Birthday Present to Medical Research	
<i>Because I am grateful for research work which has saved my life</i>	<input type="checkbox"/>
<i>Because my health has been improved by research work</i>	<input type="checkbox"/>
<i>I am sending you ONE DOLLAR for this year's birthday present.</i>	
<i>I hope I can do the same each year</i>

with which they are familiar to contribute one dollar on each birthday anniversary. Although modest in amount such contributions have provided us with considerable money.

We have thousands of diabetic patients who know that they are either alive or better because of research work on insulin and modernized diets.

W. D. SANSUM, M.D., Santa Barbara, Calif

HEAT STROKE AT BOULDER DAM

To the Editor—During the last few months I have read several articles referring to heat prostration at Boulder Dam, also the prevention of sunstroke among the men employed by the liberal use of salt and an adequate supply of drinking water. I have been connected with the work at Boulder Dam since the beginning and it seems to me that other factors must be taken into consideration besides merely the prevention as mentioned.

Boulder Dam was begun before any adequate facilities were available to house or feed the men. Many of the men were quartered at bunk houses at the river camp which was approximately 1,200 feet lower in elevation than Boulder City. The bunkhouses consisted of one large room filled with cots in which 150 or 200 men were quartered. There was no air conditioning in those days. Water was hauled from Las Vegas and often allowed to remain in milk cans and tanks for several days before it was used, or, largely, the Colorado River was merely allowed to settle a while and then drunk. There was a terrific amount of diarrhea that summer and practically every sunstroke patient had diarrhea. It was impossible to refrigerate the food properly under the existing conditions. The milk served the men was often sour.

The summer of 1931 was by far the hottest that has been encountered during the building of the dam. During July, the month the most sunstrokes occurred, the temperature in

Las Vegas reached 120 practically every day and it averaged about 10 degrees hotter in the bottom of the canyon. The worst part of the construction was under way—the driving of the diversion tunnels—and this was done without proper ventilation and with the fumes of powder smoke and gasoline trucks present.

Examinations were not done on the men before they were employed until the latter part of the summer, and as a result many physically unfit men were employed. These were the ones most susceptible to heat prostration.

The summer of 1931 was the first that any cases of heat prostration were ever recorded in Las Vegas and there were several that summer.

We were using intravenous saline therapy in the cases of sunstroke at that time in the Las Vegas Hospital and it worked well in the cases in which removal to the hospital was done before the lapse of several hours after the onset of symptoms. Las Vegas is about 33 miles away from the dam and as the men had to be transported in ambulances it was not always convenient to bring them to the hospital as soon as they should have been.

The Harvard commission was here during the summer of 1932 to study sunstroke and the effect of extreme heat on workmen and there was no sunstroke with the characteristic temperature ranging to 110 or 112. There were merely some very mild prostrations with muscular cramps. They however recommended the use of salt in the drinking water and this was done in the summer of 1933 and the following summer.

It seems to me that the secret of the high number of cases encountered in 1931 is primarily the terrific temperatures encountered, with poor food, poor water, poor housing facilities with resulting lack of sleep, lack of physical examinations, and the epidemic of diarrhea as secondary factors. The last might have had considerable to do with the dehydration in some of the cases.

J R McDANIEL JR., M D, Las Vegas, Nevada

"PSYCHOLOGIC CONCOMITANTS OF PAIN"

To the Editor—Apropos of the last paragraph in the editorial "Psychologic Concomitants of Pain" (THE JOURNAL, February 9, p 476) beginning 'There are no words in English, Critchley says, to signify the state of mind that follows the cessation of a severe or protracted painful experience,' you will be interested to know that Beethoven felt in such accord with this statement that he expressed it musically. He fell sick during the composition of opus 132 (one of his last compositions) and on recovery inserted into the work the strangely beautiful "Heilige Danksang." He felt that "convalescence" was such a mysterious sensation that it could not be expressed in the conventional musical forms so reverted to 'die Lydischen Mode.' These facts are conspicuously featured in Aldous Huxley's "Point Counterpoint."

ISABELLA H PERRY, M D, San Francisco

SENSITIVITY TO CODEINE

To the Editor—In THE JOURNAL, March 24 1934, page 908, was an article by Drs Scheer and Keil reporting a case of hypersensitiveness to codeine and stating that there were only seven proved cases on record. Since then I have seen no new reports, so I am reporting a case of mine which I think is a proved case. It made no impression on me at that time as I did not know that the condition was so rare, but the circumstances leading up to it did make a lasting impression. About eighteen years ago my brother-in-law, about 30 years old, was assisting with preparations for a wedding and was taken with a severe pain in his abdomen and applied to me for temporary

relief. I gave him one-fourth grain (0016 Gm.) of codeine, which relieved the pain but within a short time caused pruritus and a generalized eruption so severe that he could not attend the wedding. This lasted for about twenty-four hours and cleared up. About two years later he again asked for relief from some pain and I gave him one-fourth grain of codeine, with a repetition of his former experience. I have been unable to get him to take another dose of codeine, but he told me recently that a dose of morphine given at the time of an operation caused the same condition.

VACCINATION AGAINST WHOOPING COUGH

To the Editor—I would appreciate your opinion on whooping cough vaccination. Would you use the Sauer method or that described by Krueger, Nichols and Frawley? Is it feasible to use the latter in the active as well as the prophylactic treatment for pertussis? Is it as yet known how long this immunization lasts? How can I proceed to test the serum titer for immunization after inoculation is completed? How is the Frawley serum given subcutaneously or intramuscularly and how long should it take for immunity to develop? Would you recommend the vaccine of Eli Lilly & Co or of Parke Davis & Co? Please omit name.

M D, Massachusetts

ANSWER—Regarding whooping cough vaccination, there are three distinct phases: (1) the treatment by vaccines after the disease has developed, (2) the modification or prevention of the disease in those recently exposed, and (3) the active immunization of those children not exposed. The most controversy centers about the first two. It is generally acknowledged that vaccine has but little effect in the paroxysmal stage of pertussis. Many hold it to be of value in the early catarrhal stage. The majority of those who favor it recommend it after exposure and before symptoms develop. The results obtained are difficult to evaluate because of the lack of controls, but this lack of absolute proof of its efficacy is not a sufficient reason for a conscientious physician not using it. The most favorable and best controlled clinical observations are those of Madsen in the epidemics in the Faroe Islands. In the second epidemic the mortality was thirty times greater and there were sixteen times as many severe cases in the nonvaccinated group. Even with no other evidence, these reports of Madsen would justify the use of pertussis vaccine, partly to prevent the disease but especially to reduce the mortality and decrease the severity.

Frawley, Nichols and Krueger and others have developed a method by which the outer coating of *Haemophilus pertussis* is crushed and demolished. The soluble endo-antigen that is obtained is stated theoretically to have greater antigenic value, but it must yet be subjected to rigid clinical tests. Their conclusions indicate that the antigen has considerable merit both as a prophylactic and as a therapeutic measure in the treatment of pertussis. Its prophylactic value was mainly in causing very mild attacks in those in whom pertussis afterward did develop. Several careful investigators have since confirmed their work. Aldrich, beginning with 0.5 cc of antigen, administered two more doses of 1 cc on alternate days thereafter and states that although the prophylactic effect is more uncertain the antigen apparently has the definite effect of modifying and shortening a majority of pertussis infections. This fact is particularly true when the antigen is given early in the attack or before the onset of the cough. Nichols advises giving an initial dose of 0.25 cc., following with injections daily (if possible) or at least every other day of 0.5, 0.75 and finally 1 cc.

Madsen, however, reports just as favorable results with the vaccine but insists, as does Sauer, that it be made from young recently cultivated strains grown on blood agar and that the dose be large (vaccine contains 10 billion bacilli per cubic centimeter. 22 billion were given, divided into three doses). A number of nationally known pediatricians have used the Sauer vaccine, after exposure to the disease, and have concluded that, whereas they may not have been able to prevent the onset of whooping cough, the disease has been modified materially.

Certainly enough evidence has been produced to warrant giving pertussis vaccine or the antigen in nonimmune children between

the time of exposure and the onset of symptoms, in an attempt to prevent whooping cough or at least to decrease its severity.

Regarding the third consideration—the active relatively permanent immunization of those children not yet exposed to whooping cough—most experience concerns the use of the Sauer vaccine. He was the first to attempt this with apparent success. Sauer prepares his vaccine largely according to Madsen and the Danish State Serum Institute specifications, the principal difference being that he uses human blood for his blood agar plates. The total of from 7 to 8 cc. (from 70 to 80 billion bacilli) is divided into three weekly (bilateral) injections of 1, 15 and 15 cc respectively. Active immunity is completed in four months and lasts for years. The best age for immunization is the second half year of life. More observations on larger numbers of children over longer periods of time by independent observers are required to confirm this work, but enough evidence has been presented to justify the physician in carrying out this procedure in preventive medicine. Dr. Sauer recommends his vaccine only for permanent immunization. Both Madsen and Sauer stress the importance of stringent care in the preparation of the vaccine and large doses. Sauer strongly advises keeping it cold in a refrigerator and not carrying it around in one's bag for several days.

All injections are given subcutaneously.

Regarding the titer, Huenekeens, Toomey, Madsen and others were able to demonstrate that pertussis vaccine produces specific immune bodies, as shown by the complement fixation test. The only method of demonstrating immunity serologically is by the height of the complement fixation titer.

The technique of determining the complement fixation titer, the only known method of measuring the antibody content in those immunized against pertussis, is a complicated procedure, which can be performed only in a well equipped serologic laboratory and is not practical for ordinary clinical use. Details may be found in an article by J. J. Miller Jr. (*J. Immunol.* 26:247 [April] 1934).

The Council on Pharmacy and Chemistry has deferred consideration of pertussis vaccine (Sauer) until more convincing evidence becomes available (*THE JOURNAL*, March 9, p. 834).

ASTHMATIC ATTACK AFTER PERMANENT WAVE

To the Editor—I have recently seen a case of asthma that developed following a permanent wave. The materials used on the hair were Luxor oil solution and Minnie Mix wave set solution. I understand that the former solution is some bland oil and ammonia, the latter I believe is gum arabic and alcohol. I would appreciate it if you would inform me what these solutions contain and if cases of asthma have been reported following the use of them. Are there cases of gum arabic allergy? Any information that you can give me will be appreciated. Please omit name.

M D Arizona

ANSWER—Because of carefully guarded trade secrets and because the Food and Drugs Act does not include cosmetics it is next to impossible to find out what the constituents of specified brands of materials are. However, it is generally known what the usual ingredients are in such cosmetics. For dry shampoos, orris root or lycopodium is customarily employed. Allergic reactions have occurred with both. For the purpose of setting the hair after the process of waving, emulsions of various gums such as the gum of flaxseed, acacia (gum arabic), gum tragacanth, gum of quince seed, and Karaya gum (Indian gum) are commonly used. In addition, the following ingredients are used in the manufacture of hair fixers: boric acid, alkali carbonates, alcoholic keratin, perfume, petrolatum, and also several varieties of waxes.

Instances of asthma and vasomotor rhinitis to flaxseed preparations are fairly frequent. As far as we know there have been no cases reported of allergy to acacia in waving fluids, however, there are probably a number of such unsuspected instances. Two case reports dealing with acacia allergy are to be found in recent literature. One (Maytum, C. K., and Magath, T. B. Sensitivity to Acacia. *Proc. Staff Meet., Mayo Clin.* 7:216 [April 13] 1932) deals with an allergic reaction in a woman at the beginning of her second intravenous injection of a solution of acacia. The other paper tells of an instance of asthma in a man who was exposed to acacia dust in a candy factory (Spielman, A. D. and Baldwin, H. S. Atopy to Acacia, *THE JOURNAL*, Aug. 5, 1933, p. 444). Recently there has been reported a case of vasomotor rhinitis due to the use of Karaya gum solution in the hair (Bullen, S. S. Perennial Hay Fever from Indian Gum, *J. Allergy* 5:484 [July] 1934). A similar instance of asthma due to Karaya gum hair waving fluid has been reported. There are probably many more instances of this kind.

It is to be borne in mind that many of these gums, especially acacia and Karaya gum, are used in considerable amounts for other purposes such as demulcents, hand lotions in the making

of lozenges, troches "chewy" candy, calico printing and for laxative purposes. Exposure in an allergic individual may occur also from such and other sources.

If possible, the patient should be tested with the various substances mentioned. It may also be possible to find out the nature of the suspected material by testing it on a known patient. There have been several instances of flaxseed allergy.

TOXICITY OF CINCHOPHEN

To the Editor—1 In view of the recent warnings about the toxicity of cinchophen preparations, what is the consensus as to its indications, contraindications and dosage, average and maximum in cases of gout? 2 In a specific case, my patient is a man aged 63. He has typical gouty attacks which have recently come with increasing frequency, involve singly either of the great toe joints or knee joints, last from a few days to one week and disappear. Between attacks the blood uric acid readings have been 8 and 6 mg. per hundred cubic centimeters respectively before and after the use of purine free diets. The rest of the blood chemistry is normal. There have been no gouty tophi discovered at any time. The only other changes of note are a blood pressure of 160 systolic and 110 diastolic and a fixed specific gravity of the urine as shown by a Musenthal test to be from 1.016 to 1.018 coupled with a history of nocturia. What dosage of cinchophen is warranted during the attacks? Is the high uric acid between attacks an indication for giving cinchophen during these periods? If so in what dosage? 3 Moreover, in view of the warnings in recent literature, might the use of cinchophen followed by toxemia and death have any medicolegal aspects? Kindly omit name.

M D New Jersey

ANSWER—1 New and Nonofficial Remedies 1935, states that while the ordinary doses of cinchophen are usually harmless they are occasionally followed by severe and even fatal effects, which are more frequent with the larger doses. Excessive dose, or the long continued use of moderate amounts may cause damage to the kidney and occasionally give rise to acute yellow atrophy or to dangerous or fatal hepatitis, usually characterized by the late and relatively abrupt onset of symptoms, the most frequent being jaundice. Fewer cases of poisoning have been reported after neocinchophen, but the relative danger of these two substances has not been determined satisfactorily. The average dose of neocinchophen is 0.3 Gm. which may be given every two to four hours as required for relief of pain, although in the treatment of rheumatic fever, when used as a succedaneum of salicylate, it has been given in a dosage as high as 1 Gm. every hour until relief has been secured. The appearance of a skin eruption should prompt its immediate discontinuance. In any case it should not be given continuously but in brief courses with longer intervals to secure complete elimination.

2 In gout the use of neocinchophen is justified in doses of 0.5 Gm. from four to six times daily. It makes the kidney more permeable to uric acid so that more uric acid is excreted, and less is found in the blood. Its greatest effect on uric acid elimination is reached in one day. It should be discontinued after the second day, as it does not "mobilize" uric acid in any sense of the word. It has its best use in gout when employed between attacks in courses of two days each. Given this way, it might abort threatened attacks. During an attack it should not be given, as uric acid is then being eliminated as rapidly as is possible.

3 When he gives it with proper precautions, the physician carries no more liability in the prescribing of this than he does of any other potent agent.

SPLENOMEGALY

To the Editor—I am interested in a 3 year old boy who was suffering from severe rickets when I first examined him three months ago. He had bony changes of marked degree in the skull and chest. There was a pot belly with enlargement of the liver and spleen. He also suffered from repeated attacks of gastro-intestinal irritation accompanied by fever. This condition had been present for more than a year with lack of a persistent plan of treatment. Under viosterol and ultraviolet therapy the gastro-intestinal symptoms have cleared up and his general health has improved considerably. The liver has diminished in size to almost normal proportions. The spleen remains enlarged. His skin is tough and scaly and the quartz light therapy has been discontinued. Can you venture an opinion on these facts as to the splenomegaly? Will it recede to normal size in time? I believe that a blood dyscrasia has been ruled out by a blood count. The Wassermann reaction is negative. How long should viosterol or cod liver oil be continued in such a case? Please omit name and address.

M D Pennsylvania

ANSWER—The question of enlargement of the spleen in rickets has been debated by clinicians for years. The fact that splenomegaly may occur in a rachitic infant has been used by some European clinicians to support the toxic or bacterial theory of the etiology of rickets. Various authorities give the incidence of splenic enlargement in rickets in variable figures. These vary from 20 to 70 per cent. The late Alfred Hess collected some valuable clinical data on this point some years ago. He found that in a large series of infants with negative

Wassermann reactions the spleen was palpable in 20 per cent of those who gave no evidence of rickets and in 25 per cent of those who were rachitic. Starek corroborated these observations pathologically. This investigator noted the size and condition of the spleen in 113 necropsies of young children who died from various causes. The spleen was found to be enlarged in (4) per cent of the rachitic cases and in 50 per cent of non-rachitic cases. Unfortunately there are no accurate scientific data on the cause of the splenomegaly. The fact that it does not recede on antirachitic therapy throws considerable doubt on the rachitic etiology. The consensus is that enlargement of the spleen in rickets is the result of infection or at any rate secondary to it. Clinical experience has shown that such spleens gradually recede to normal size with general treatment. However, the time required for this change may be a matter of years. Such a case should receive careful consideration as to other causes of splenomegaly. Cod liver oil or viosterol should be continued in therapeutic doses until roentgenographic and blood chemistry observations are normal. From this time on prophylactic doses should be continued throughout the period of growth. Splenomegaly should not be used as a criterion for antirachitic therapy.

TREATMENT OF SYPHILIS

To the Editor—I have a Jewish patient aged 55 a woman who has presented a four plus Kahn reaction. There have been no distinct clinical symptoms indicating the presence of the disease or to serve as an indicator of the progress of the treatment. To date she has had twenty four intramuscular injections of a bismuth compound one course of mercury injections six months of iodides orally and about ten injections of arsenamine in doses ranging from 0.2 to 0.6 Gm. Severe reactions and eczema have prevented this medication after several trials. Sodium thiosulphate has been used freely intravenously and orally. The Kahn reaction now is two plus and she is becoming discouraged. What can I give her to take the place of the arsenic preparation that may speed a cure? I will appreciate any suggestions in handling the entire course of the case.

M D Florida

ANSWER.—There appears to be no reason for discouragement on the part of this patient. It is the doctor who should be discouraged from attempting to "cure" a disease of many years standing by too heroic treatment. In a woman of 55 intensive arsenical treatment may be far more dangerous than a persistent positive Kahn test. Patients can live many years with a positive serologic test without impaired usefulness. Intermitent treatment with courses of bismuth compounds and iodides may ultimately bring about a reversal of the Kahn test. Even a negative Kahn test should not be looked on as a criterion of absolute "cure" as the results of postmortem studies (Wartlin) have shown. A careful cardiovascular examination and a spinal puncture will give valuable information and should precede any further therapeutic efforts.

DIAGNOSIS OF DERMATITIS

To the Editor—A white married woman aged 28 complains of a scattered eruption over her body and face of eight years duration. The eruptions are more pronounced just before the menses. She also complains of sore breasts just before her periods. The eruption she states starts as a small hard pimple which gets larger and a watery secretion is discharged from each pimple which is very itchy. The patient has very small breasts a high arched palate and a male hair line. Her height is 5 feet 7 inches (170 cm) her weight 151 pounds (68.5 kg). Systemic examination is negative. She has a pelvic-girdle obesity. Menstruation started at 14 years. She flows regularly every thirty two days for only one day and only stains. The eruptions are papular and hard with some induration at the base. The blood chemistry, Wassermann reaction and urinalysis are negative. Basal metabolism has been minus 18 on three different tests. The vaginal examination reveals a small uterus not inflexible the ovaries are not palpable. She was treated with thyroid and pituitary with no results in weight eruption or menses. She was treated with antitriptin S and theelin for three months. The menses increased to three days and in amount. Soreness of the breasts was absent and no weight loss was noted. The eruptions are the same. This is the most annoying symptom. I am at a loss to make a diagnosis as to the skin condition. If possible kindly give me a diagnosis and suggest treatment. Kindly omit name.

M D Rhode Island

ANSWER.—It is impossible to make a dermatologic diagnosis from the description given. In view of the definite evidence of endocrine disturbance, the dermatitis might be of endocrine origin, such as, for instance a dermatitis dysmenorrhoeica (Pollard Matzenauer). If an endocrine disturbance is causally related to the dermatosis, the effort at correcting this underlying condition should be persisted in. However the dermatitis described could well be completely unrelated to the menstrual and hormone disturbances and in this event many possible diagnoses are to be considered. The first and foremost seems to be either a drug eruption or a dermatitis from external contact. Absolutely all drugs should be stopped for at least two months.

Even the question of eliminating iodized salt from the table and kitchen should be carefully gone into. The search for possible external irritants should be carried out by means of the patch test the technique of which may be found in the article on the contact or patch test in dermatology by Drs Marion B Sulzberger and Fred Wise in the *Archives of Dermatology and Syphilology* 23 519 (March) 1931. Locally the two following may be tried.

1 Menthol 0.25 per cent, phenol 1 per cent coal tar solution 10 per cent in calamine lotion with zinc oxide.

2 Menthol 0.25, naftalan 10 per cent in Lassar's paste.

ALCOHOL IN PEPTIC ULCER

To the Editor—What clinical evidence exists that alcohol such as a highball or whisky well diluted with water or beer is harmful to ulcer patients? Kindly do not publish name.

M D Georgia

ANSWER.—It is generally conceded that alcohol in any form should not be taken by patients with peptic ulcer. Alcohol is an irritant to the gastric and duodenal mucosa. Hurst and Stewart (Gastric and Duodenal Ulcer New York Oxford University Press p 422) state that while light wines or well diluted whisky may be taken with meals after the patient is free from symptoms for several months cocktails, whisky champagne and other effervescent alcoholic drinks must be prohibited. Furthermore 7 per cent alcohol in water is one of the test meals in use for the determination of gastric acidity because of the well known ability of alcohol to stimulate acid secretion. Edward L Kellogg (The Duodenum, New York Paul B Hoeber Inc, 1933, p 540) states that the abuse of alcohol among other factors, may lead to the recurrence of an ulcer.

MERALGIA PARAESTHETICA

To the Editor—A boy aged 11 years who has been under my care a short time has suffered since he was 5 from a painful area on the outer side of the left thigh about 2½ inches above the knee joint. This area of tenderness is about 2½ inches long and 1½ inches wide. It is not inflammatory. There is no trouble with the deeper bone or soft parts. There are no apparent pathologic changes. The area referred to is exceedingly sensitive the clothing rubbing on it causing pain. A mere touch will cause excruciating pain. It gives him lots of trouble in school. My diagnosis is meralgia paraesthetica or Roth's disease. The anterior crural nerve on that side seems tender. The tonsils have been removed. They were not normal. All organs have been examined. Kindly give your opinion as to diagnosis and treatment. Please use initials only.

M D California

ANSWER.—The area described corresponds with the usual site of meralgia paraesthetica in the distribution of the external cutaneous femoral nerve. The causes are usually traumatic or toxic. Search should be made for causes of pressure on the nerve, including tight clothing and suspenders. Among toxic causes, in addition to sources of focal infection, the possibility of lead intoxication should be considered. These, of course, presuppose that such conditions as disease of the vertebrae and spina bifida have been excluded. Therapeutic measures other than removal of an established cause include the use of mild galvanism, local applications of heat and such measures as diathermy, though in chronic cases they may not accomplish much. The condition is not serious in itself, but the pain and incapacity may be so severe as to justify section of the cutaneous nerve involved.

EOSINOPHILIA IN BRONCHIAL ASTHMA

To the Editor—Would you kindly give me the latest data on the significance of eosinophilia in connection with bronchial disturbance? Has any treatment been suggested in connection with the high eosinophil count?

IRVING G CLARK, M D Columbus, Ohio

ANSWER.—Eosinophilia or an increase in the number of polymorphonuclear eosinophils in the blood above 4 per cent, has many causes. The most common causes are (1) trichiniasis (2) allergic conditions (3) bronchial asthma (4) intestinal parasites (5) skin diseases, especially urticaria, psoriasis, pemphigus and arsenical dermatitis (6) scarlet fever, (7) bone marrow diseases, especially myelogenous leukemia metastases tuberculosis or osteomyelitis, (8) Hodgkin's disease, (9) liver therapy and (10) familial conditions.

It is probable that all the causes of eosinophilia except the group due to bone marrow involvement belong to the series of allergic conditions. For instance it is found in bronchial asthma, hay fever, urticaria, angioneurotic edema serum sickness, and after the injection of vaccines and various foreign proteins.

In true allergic bronchial asthma, eosinophils are found in large numbers in the sputum as well as in the blood. Eosinophilia does not occur in cardiac asthma and is therefore of differential value. Eosinophils are found in the conjunctival smears in hay fever and in the skin, lymph nodes and internal organs in various allergic states.

The presence of an eosinophilia in a bronchial disturbance therefore speaks for a true bronchial asthma, when intestinal parasites and bone marrow diseases can be excluded. The eosinophilia does not require treatment, as it is most probably evidence of some defensive reaction to a foreign protein or chemical substance. Removal of the exciting agent (pollen, food, arsenic, camphor, parasites) will cause the eosinophilia to disappear, except in the rare cases of familial eosinophilia of unknown cause.

BONE UNION BY BONE CEMENT

To the Editor—May I ask you kindly to supply me with information on the subject of bone union by means of bone cement or bone glue or any other substance to be inserted or injected between bone fragments for the purpose of uniting these. I am not interested in transplants or fixation of fractured bone. Kindly inform me of any existing literature pertaining to this subject whether it has been in clinical use or in the form of research. Kindly omit name.

M D California

ANSWER—The correspondent imposes severe limitations on the answer. Exclusive of the transplantation of bone or fixation of fractured bone, one might say that all methods are still practically in the experimental stage.

These methods include those grouped as chemical and those called organic. The chemical ones include the addition of some combination of calcium and phosphorus, such as dicalcium phosphate or tricalcium phosphate. This method has been used by Clay Ray Murray of New York and by Farrell at the New York Orthopaedic Hospital.

The organic methods include bone dust and bone paste. Bone drilling such as that designed by Beck of Kiel and popularized by Böhler should be mentioned in this connection, that is, multiple drill holes are made across the area of delayed union in order to stimulate circulation and to produce avenues for the passage of osteogenic elements.

The correspondent may be interested in the following two articles.

IRIDOTASIS AND IRIDENCELEISIS

To the Editor—In THE JOURNAL, January 26 page 341 is given a somewhat incorrect answer to a correspondent who inquires concerning the derivation of the terms iridotasis and iridencleisis. The second element of each word being very unusual in medical terminology might well be expected to lead a busy physician or editor who has no leisure for furishing his Greek to philosophize a little as many of us are tempted to do in the absence of exact information. Since the former word is neither a simplification nor a corruption and since the origin of the latter is (despite your cautious assertion to the contrary) perfectly clear I will venture to establish their legitimacy. Both are modern formations sired by respectable though little known Greek words properly united and are appropriate to the operations they were designed to describe.

Iridotasis is a compound of *irido-* which is the combining form of *iris* plus *tásis* stretching (from *τείνω* to stretch). The element *tasis* has nothing to do with the *desis* of *iridodesis* though the operations intended by *iridotasis* and *iridodesis* are similar. The origin of the second element of the latter is to be found in *δέω* binding (from *δέω* to bind). In view of frequently heard mispronunciations it is worth mentioning that these words should be uttered with the stress on the antepenultimate syllable *irido-tas-is* and *irido-cle-is-is*.

Iridencleisis runs parallel in its formation. The first element is the same except for the *-o-* which is needed only before a consonant. The second element is itself compounded from two words *ἐλ* in and *κλέω* to shut or lock. The meaning, therefore is a locking in of the iris and whereas the other terms mean respectively a stretching of the iris and a binding of the iris. Once again attention should be directed to the stress *iriden-cle-is-is*. The *ei* is sounded as in *height*.

It may be of interest to your correspondent and other readers to know that the term *iridencleisis* can be traced back to Sir William Adams who used it in 1812 to designate his operation for making an artificial pupil. George Critchett of London in 1857 introduced the erroneously compounded term *iridensis* (corrected to *iridodensis* by later writers who respected the Greeks way of combining Greek words) for his glaucoma operation. In 1906 S. Holth of Christiania Norway proposed another glaucoma operation which he called *iridencleisis antiglaucomatosa* and shortly afterward Johan Borthen of Bergen Norway described his *iridotasis antiglaucomatosa*. In the *Archiv für Augenheilkunde* 68: 145 1911 Bothen gives the derivation of his newly coined term.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY. Written (Group B candidates). The examination will be held in various cities throughout the country April 29. Oral (Group A and Group B candidates). New York June 10. Sec. Dr C Guy Lane 416 Marlborough St. Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY. Final oral and clinical examination (Group A and Group B candidates). Atlantic City N J June 10-11. Application lists close May 1. Sec. Dr Paul Titus, 1015 Highland Bldg Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY. Philadelphia June 8 and New York June 10. Sec. Dr William H Wilder 122 S Michigan Bldg., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY. New York June 8. Sec. Dr W P Wherry 1500 Medical Arts Bldg Omaha.

AMERICAN BOARD OF PEDIATRICS. Atlantic City N J June 10 and St Louis Nov 19. Sec. Dr C A Aldrich, 723 Elm St Winnetka, Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY. Philadelphia, June 7-8. Sec. Dr Walter Freeman 1726 Eye St N W Washington D C.

AMERICAN BOARD OF RADIOLOGY. San Francisco May 10-12 and Atlantic City N J June 8-10. Sec. Dr Byrl R Kirklm Mayo Clinic, Rochester Minn.

ARKANSAS. Basic Science. Little Rock May 6. Sec. Mr Louis E. Gebauer, 701 Main St Little Rock. Regular. Little Rock, May 14. Sec. Dr A S Buchanan Prescott. Eclectic. Little Rock, May 14. Sec. Dr L L Marshall 820 W 14th St. Little Rock.

CALIFORNIA. Reciprocity. San Francisco May 15. Sec. Dr Charles B Pinkham 420 State Office Bldg Sacramento.

IOWA. Iowa City June 4-6. Dir Division of Licensure and Registration Mr H W Greife Capitol Bldg, Des Moines.

KENTUCKY. Louisville June 5-7. Sec. State Board of Health Dr A T McCormack 532 W Main St Louisville.

NATIONAL BOARD OF MEDICAL EXAMINERS. The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination June 24-26 and Sept. 16-18. Ex Sec Mr Everett S Elwood 225 S 15th St Philadelphia.

NEBRASKA. Basic Science. Omaha May 7-8. Dir Bureau of Examining Boards Mrs Clark Perkins, State House Lincoln.

NEVADA. Carson City May 6. Sec. Dr Edward E. Hamer Carson City.

OHIO. Columbus June 4-7. Sec. State Medical Board Dr H M Platter 21 W Broad St Columbus.

OREGON. Basic Science. Portland May 18. Sec. Mr Charles D Byrne, University of Oregon Eugene.

WYOMING. Cheyenne, June 3. Sec. Dr W H Hassel Capital Bldg Cheyenne.

New York September Examination

Mr Herbert J Hamilton, chief, Professional Examinations Bureau, reports the written examination held by the New York State Board of Medical Examiners in Albany, Buffalo, New York and Syracuse, Sept. 24-27, 1934. The examination covered 9 subjects. An average of 75 per cent was required to pass. Two hundred and seventy-one candidates were examined, 205 of whom passed and 66 failed. The following schools were represented.

Book Notices

Aids to Psychiatry By W. S. Dawson M.A. M.D. F.R.C.P. Professor of Psychiatry University of Sydney Third edition. Cloth. Price \$1.50. Pp. 318. Baltimore: William Wood & Company 1934.

This little book is one of the few compendiums in psychiatry that are at all adequate. It is interesting to note that in it the neuroses are given proportionately greater space than the more serious mental disorders, an unusual but intelligent balancing of subject matter not usually found even in the larger psychiatric textbooks. The book is reasonably accurate according to conventional psychiatry, for there is nothing even approaching the radical in it. It might well be considered a summary of any of the more acceptable textbooks of psychiatry and so as a review book, should adequately serve its purpose. The stress that is placed on amnesia (feeble-mindedness) makes these chapters well worth perusing even though the psychologic factors in this type of condition are not stressed as much as they would have been had the book been written by an American. The chapter on treatment is short and probably of little value in the actual handling of patients but sufficiently detailed to enable a medical student to gather much theoretical information about the subject. The British terminology and medicolegal materials are used throughout, and the last chapter on case taking is probably too abridged. One who approves of these shortened textbooks will find this volume satisfactory. There is a question, however, whether simply giving a list of definitions without illustrations and without case histories is ever adequate in the training of students in psychiatry. Considering its price and the amount of material in it it should be sufficiently useful for a psychiatric teacher to have in his library even though he already has the more formal textbooks. For the busy general practitioner, it may contain just the clues he needs in recognizing the various serious mental disorders.

Handbuch der Biochemie des Menschen und der Tiere Herausgegeben von Prof. Dr. phil. et med. Carl Oppenheimer. Band II. Ergänzungswerk. Ergänzung zu Band IV-VI des Hauptwerkes. Second edition. Paper. Price 71 marks. Pp. 961 with 41 illustrations. Jena: Gustav Fischer 1934.

As a supplement to volumes IV-V of the original work this is a valuable addition, which specialists in the various fields will no doubt welcome. The subdivision of subject matter adopted naturally leads to considerable overlapping in the treatment by the authors. On the whole, the reviews appear to cover quite completely the more important contributions over the period 1925-1932 inclusive. The main divisions adopted are chemistry of tissues and organs, secretion and products of secretion, digestion absorption and excretion, and nutrition, gas exchange and metabolism.

In the first section, Ludwig Pincussen presents carefully selected citations on general physical chemistry and the organic and the inorganic constituents of the blood. Edgar Wöhlich rather briefly reviews blood coagulation. H. K. Barrenscheen presents blood sugar fully. Wohlgemuth reviews blood enzymes other than the Abderhalden reaction. Wertheimer

Ohio December Examination

Dr. H. M. Platter, secretary Ohio State Medical Board, reports the oral, written and practical examination held in Columbus, Dec. 3-6, 1934. The examination covered 10 subjects and included 80 questions. An average of 75 per cent was required to pass. Thirty-six candidates were examined all of whom passed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Georgetown University School of Medicine (1934) 84.5		(1932)	81.9
Loyola University School of Medicine (1934) 80.7 * 81.3 * 82.2 * 83.2 * 84 *		(1933)	81.6
Northwestern University Medical School	(1929) 80.9	(1930)	83
Boston University School of Medicine		(1933)	79.5
Harvard University Medical School		(1934)	85

* Verification of graduation in process

covers the latter fully. Gerhartz presents three sections on the chemistry of lymph, the chemistry of transudates and exudates, and the chemistry of the postembryonal organs involved in blood cell formation. R. E. Mark discusses the formation of lymph. Aron and Klinka have assembled much information on bone, teeth, cartilage and elastic tissue. Stephan Rothman gives a comprehensive review on the skin. Paul Krüger has gathered and organized information concerning supporting tissues from the chemical and developmental points of view. In the discussion of the composition of muscle tissue, Otto Fürth covers proteins, amino acids, simple bases and the physical chemistry of muscle tissue. Karl Lohmann reviews the fats, lipins and carbohydrates and H. K. Barrenscheen considers the purines. Lohmann and Weicker give a brief review on heart and blood vessels. Pincussen covers the chemistry of lung tissue. Gottschalk reviews the chemistry of tumor, cancer and sarcoma tissue. Kurt Steindorff gives a well organized treatment of the chemistry of the eyeball.

In the second section there are good reviews by Julius Wohlgemuth, Bickel, Theodor Brugsch and Paul Krüger on the chemistry of salivary, gastric, pancreatic and intestinal secretions and special sections on the liver and bile and digestive glands in the lower forms. Under the general title of sex glands, Gerhartz presents an exceedingly brief treatment of the testicle. Leo Zuntz likewise ignores the hormones in the female sex organs. Paechtner reviews the chemistry of the resting and incubating egg and Grimmer gives well organized reviews on the mammary gland, milk and milk coagulation.

In the third section the chemistry of digestion and absorption in invertebrate forms is reviewed by Arthur Schcinert, absorption by Pincussen, the formation and composition of feces by Miss Kozwianek, skin excretion by Rothman, excretion by tears by von Röttli, poisonous excretion by T. A. Maass, the action of the kidney under various influences by R. E. Mark, the chemistry of the kidney of urine and the physical chemical aspects of the latter by Pincussen, the chemistry, origin and amount of amniotic fluid by Leo Zuntz, the gases of the body and their circulation therein by Lehmann, and the acid-base equilibrium by Gollwitzer-Meier.

In the fourth section Hans Aron and Karl Klinka cover the advances in the general aspects of nutrition. von Wendt briefly reviews the theoretical principles of metabolism. Lehmann reviews two subdivisions, the respiratory and general exchange and the energy exchange in the organism and Grafe concludes the work with a timely and extensive review on the specific dynamic action. Fortunately an excellent index is included in this extensive supplement.

Jewish Contributions to Medicine in America (1856-1934) with Medical Chronology and Bibliography. By Solomon R. Kagan, M.D. Cloth. Price \$5. Pp. 549 with 69 illustrations. Boston: Boston Medical Publishing Company, 1934.

This book has a delightful foreword by the medical historian Dr. James J. Walsh, together with a preface and introduction by the author. The first chapter is devoted to brief biographies of early colonial Jewish physicians in America but in the remainder of the book physicians are classified according to their various specialties. In the appendixes the special work of certain physicians is described under the title of "Medical Lights." Then follow a list of Jewish medical institutions and their history, a section on Jewish medical philanthropy and finally a medical chronology and a bibliography together with dates of persons, names and subjects. The illustrations consist of reproductions of photographs of the respective physicians but this represents only a small percentage of the many names listed. The biographies are in some instances extensive and in others brief but the work as a whole gives one a good idea of the great work that has been done in America from colonial days onward, together with the institutions that have been developed. The work is a valuable one from a historian's standpoint and it should prove useful to any one who is interested in medical history. The accomplishments of many of the American Jewish physicians will be a source of pride to those who are interested in the achievements of their own people and a source of information to every one. There are a number of typographic errors but these are not sufficient to detract from the value of this timely work.

Body Mechanics in the Study and Treatment of Disease. By Joel E. Goldthwait, M.D., LL.D., Member of Board of Consultants, Massachusetts General Hospital; Lloyd T. Brown, M.D., Instructor, Orthopaedic Surgery, Harvard Medical School; Loring T. Swaim, M.D., Instructor, Orthopaedic Surgery, Harvard Medical School; and John G. Kuhns, M.D., Assistant in Orthopaedic Surgery, Harvard Medical School. Cloth. Price \$4. Pp. 281 with 99 illustrations. Philadelphia & London: J. B. Lippincott Company, 1934.

In this work some of the leading orthopedic surgeons of the Boston group have combined to present modern views of posture. One finds, however, in the preface the term "chronic patient"—a rather doubtful combination coming from Boston. The book includes sections devoted to the mechanics of the body, to various types of body, and then to disturbances of various systems of the body associated with wrong body mechanics. The final chapters include treatment, illustrative cases, visceral disturbances and references to medical literature. The book is handsomely illustrated with roentgenograms and diagrams which add greatly to the value of the text. It does much to show how modern orthopedic surgery may be of aid in overcoming many common disturbances of health and also to bring relief in conditions in which body mechanics is usually not considered at all or else in a subsidiary manner. In the concluding paragraph the authors refer to "chronic medicine," meaning no doubt the diagnosis and treatment of chronic diseases. It is a locution that merits correction in future editions of this most useful work.

Notes on Dr. Camp's Lectures in Neurology Arranged by Dr. L. H. Hiler, Department of Neurology, University of Michigan. Cloth. Price \$1. Pp. 260 with illustrations. Ann Arbor, Michigan: Edwards Bros. Inc., 1934.

This is a small volume produced by the new method of litho printing which makes the text look as though it had been well typewritten. It contains summaries of lectures given in neurology at the University of Michigan and would naturally have the fault of being second-hand material although one may be sure that Dr. Camp himself must have checked the book before permitting its publication. Except for students at that particular university, it is difficult to see any single group for which this book would be more useful than other short textbooks. The descriptions of diseases are too short as a rule to be a substitute for even the smaller standard neurologic textbooks. Some of the more obscure diseases are dealt with in such a way that not even the most elementary signs and symptoms are enumerated. In all probability they should either have been omitted or a little bit more thoroughly discussed. The abridgment of the discussions of the more complicated neurologic entities would make it necessary for the student to hear Dr. Camp's lectures or else supplement this book by a larger textbook in order for instance, to see what is meant by such symptoms as the Babinski sign, the Argyll Robertson pupil and other signs which are characteristic of specific disorders but which are not fully discussed under those disorders or elsewhere. The first part of the book, dealing with the methods of examination, is too sketchy and hence is misleading to the beginning student of the complex science of neurology. The material in it is not given in any detail and the significance of individual tests, as indicated, is minimized. Nevertheless, besides the unquestionable value of the book to the specific students at whom it is pointed, many neurologists should find it valuable as a systematic outline to use to balance their own lectures. The general practitioner who has a fair groundwork in neurology might find the book valuable for review or for a quick checkup of symptoms, for what material is given is authentic and specific.

A Textbook of Pathology for Nurses By Coleman B. Rabin, B.S., M.D., Lecturer in Pathology in the Mount Sinai Hospital School of Nursing. Cloth. Price \$1.75. Pp. 243 with 61 illustrations. Philadelphia & London: W. B. Saunders Company, 1934.

This edition represents an improvement in the textbooks of pathology for nurses. Like other books, however, the purpose appears to give pathology in altogether too concise form. Each chapter is supplemented by a series of simple review questions. A notable feature of the volume is the accompanying illustrations and diagrams, in which most books for nurses are lacking. The style is simple and clear. The section on general pathology may be considered adequate, but that on neoplasms is much

too brief. Perhaps undue emphasis is placed on the results of obstruction to which five chapters are devoted. The second part is devoted to clinical pathology, presented also in illustrated form. Instructors in training schools will find an improvement in this edition largely because of the illustrations.

Symposium on Silicosis. Edited by H. F. Hueblich. Claims Manager, Employers Mutuals, Wauwatosa, Wisconsin. An Unofficial Transcript of the Silicosis Symposium Held in Connection with the Trudeau School of Tuberculosis at Saranac Lake, N. Y., June 18 to 22, 1933. Paper, Price \$4. Pp. 99 with 2 illustrations. Wauwatosa, Wisconsin: Employers Mutual Liability Insurance Company, 1934.

Because of the great importance the pneumoconiosis and especially the silicosis problem have assumed within the past few years, the Trudeau School of Tuberculosis devoted one week of the regular 1934 course exclusively to silicosis and tuberculosis. The symposium was under the direction of L. L. Gardner. The etiology of silicosis was presented by R. R. Jones of the U. S. Public Health Service, who emphasized that crystalline silica was the essential causative factor. D. L. Cummings of the Saranac Laboratories described dust measurements, emphasized the importance of routine medical examinations and stated that demonstrable silicosis generally occurred after more than five years exposure to concentrations of pure silica in excess of 5,000,000 particles per cubic foot. The third paper, by Gardner, is much the most complete and perhaps the most important of the series. His own work is tersely reviewed, and much interesting and informative data are added on the relation of tuberculous infection to silicosis. The fourth paper, on occupational history, was given by Cummings, who was followed by Henry K. Kessler of Newark, N. J., who discussed clinical aspects and physical examination. This paper provoked an especially interesting discussion on the degree of disability attending silicosis—a vexing subject on which William S. McCann of Rochester, N. Y. wrote more fully in the last section of the booklet. H. L. Simpson of the Trudeau Sanatorium and H. K. Pancoast of Philadelphia each contributed to the roentgenology of silicosis. Philip Drinker of Harvard described engineering methods of prevention, and A. J. Lanza closed the symposium with an eloquent and timely plea for careful medical control with the pointed suggestion that executives whose employees risk silicosis would do well to interest themselves in preventive measures and in sensible legislation. Dr. Gardner is to be congratulated on this symposium, and the Employers Mutuals on making the several lectures available in book form. However, the transactions do not measure up to the standards of the work of the several speakers, with the possible exception of Gardner's own contribution. Also it is hoped that future editions of these symposiums will contain summaries.

Die Mikrogasanalyse und ihre Anwendung. Von Dr. Heinrich Schwarz. Privatdozent an der Universität Wien. Monographien aus dem Gesamtgebiete der Mikrochemie. Paper. Price 21 marks. Pp. 286 with 52 illustrations. Vienna & Leipzig: Emil Halm & Co. 1933.

The author covers all well known methods of gas analysis in this volume, as well as the purely micro methods of Krogh, and includes a description of the various methods of determining the gas content of fluids. Most emphasis is placed on the manometric methods of Van Slyke and Neill to which fifty-five pages are devoted. The usefulness of the methods in biologic and physiologic problems is covered. The work includes all necessary tables to aid calculation. The author writes in a style that is easily read or translated. The format of the book is good and the illustrations are adequate.

Doctor Moon. By Catherine Meadows. Cloth. Price \$2.50. Pp. 313. New York: G. P. Putnam & Sons, 1935.

This is a novel based on the life of the famous Harvey Hawley Crippen. The Crippen case is one of the most important in criminology, deriving its interest from the medical background of the murderer and from the fact that the radio was used in his capture. The novel provides not only an excellent picture of its period but also a fine psychologic study of the murderer and of the events leading up to the crime. The book is written in a calm manner, which adds much to its suspense and therefore to its interest. The sequence of the events leading certainly toward a situation in which murder seems inevitable is established by the author with extraordinary understanding.

Physiopathologie des traversées chimiques et bactériennes dans l'organisme. Par Noël Flessinger, professeur de pathologie expérimentale et comparée. Paper. Price 45 francs. Pp. 370, with 10 illustrations. Paris: Masson & Cie, 1934.

This volume, based on a course of lectures, is devoted to the consideration of a varied group of phenomena involving the passage of substances through cellular membranes (except the absorption of the products of digestion). Among the subjects treated are the metabolism of proteins, carbohydrates and fats, the role of the liver, kidneys and endocrine organs in regulating the composition of the blood, and disturbances of the passage of materials resulting in gout, icterus, uremia, anuria, polyuria, edema and other conditions. In addition there are chapters on the passage of dyes, of large particles, of bacteria and their toxins, and of heavy metals (mercury, bismuth, gold). The subjects of immunity, allergy and anaphylaxis are discussed from the point of view of the physiology and pathology of passage. In most cases the author dwells not only on the experimental aspects of the question but also on the clinical applications. Unfortunately there is no subject index, and although the author index contains an impressive list of more than 600 names, not a single bibliographic reference is given, thus greatly decreasing the value of the volume to the serious student and to the investigator.

Medical Tactics and Logistics. By Colonel C. S. M. Blech, Medical Reserve Corps, U. S. Army, and Colonel Charles Lynch, Medical Corps, U. S. Army. Reprint. Cloth. Price \$4. Pp. 205. Springfield, Ill. & Baltimore: Charles C. Thomas, 1934.

This book is a somewhat natural continuation of the work of the principal author, who several years ago brought out a little book on map reading which still holds its place among military textbooks. Since that time he has published a manual on topography and a number of monographs in military medical journals on the strategic value of the medical service in war. The present book is the formulation of ideas developed in years of service and research in peace and war and must be accepted as authoritative. It lays a scientific foundation for the philosophy of organized military-medical service in war and exemplifies the practical application of this doctrine by a vivid presentation of diverse phases of an imaginary war on American soil. Technical comments aid the student in overcoming difficulties to be anticipated in future military operations of magnitude. A unique and useful feature of the book is a glossary of military terms, which heretofore has been lacking in military textbooks. Four topographic maps accompany the book. The suggestions in the text as to the way of making use of the maps are almost superfluous as the maps show the various battlefields even chorographically. The book is a valuable contribution to military literature, as is demonstrated by the acceptance of the dedication by the authors to former Surgeon General Ireland and the foreword by Surgeon General Patterson. It is an almost indispensable addition to the medicomilitary library.

Through the Patient's Eyes: Hospitals, Doctors, Nurses. By Slater John Gabriel, R.N., A.B. Hospital Consultant and Educational Director, Sisters of Charity of Providence. Cloth. Price \$1.50. Pp. 264. Philadelphia: London & Montreal: J. B. Lippincott Company, 1935.

The author of this book has had an extensive experience in nursing administration. Her volume, which is planned primarily for nurses, is intended no doubt to improve the hospital morale and to lead nurses into a better appreciation of the patient's point of view. She considers as well the question of what the patient is to be told, the attitude of friends and relatives, and the general subject of service in the hospital.

Introduction to Physiological Chemistry. By Meyer Bodansky, Ph.D., Director of Laboratories, John Sealy Hospital, Galveston. Third edition. Cloth. Price \$4. Pp. 662 with 39 illustrations. New York: John Wiley & Sons, Inc. London: Chapman & Hall Ltd., 1934.

The general plan of the previous edition has been followed in the rewriting of this book. Much of the material has been extended to include the more recent advances. The confirmation of the isolation of urease, the isolation of trypsin and the study of these isolated enzymes is discussed in the present edition as is also the importance of secretion of mucus in the reduction of gastric acidity. In the case of the vitamins there is much general knowledge but in a few instances the author's

ideas of therapeutic value are quite optimistic. The section on hormones has been rewritten to include analysis of crystalline insulin and a discussion of the importance of the adrenal cortical hormone. Approximately a hundred pages has been added to the text. The book is replete with bibliographic references, which enhance its usefulness. The discussion is presented in simple, understandable style. The book is not of a type suitable for clinical teaching but is one that should serve well the needs of the basic science or medical student.

Medicolegal

Pneumoconiosis Attributed to Inhalation of Coke Dust.—Grammer was employed as a still cleaner by the Mid-Continent Petroleum Corporation. The work of a cleaner was to rake down coke burning or smoldering, in stills that escaped the mechanical rake, and sweep it out. The breaking up of these coke deposits gave off dust and a trace of gases. Grammer worked steadily in that capacity for about ten years, at the expiration of which time he became ill and died. His physician diagnosed his condition as pneumoconiosis. The widow of the workman, as the administratrix of his estate, brought a common law action against the Mid-Continent Petroleum Corporation for the workman's wrongful death alleging that the corporation failed to provide Grammer with a reasonably safe place in which to work and with reasonably safe appliances with which to work and that it failed to warn or to instruct him with respect to the dangers incident to the work. The trial court, at the close of the plaintiff's evidence, directed a verdict for the defendant, and the plaintiff appealed to the United States circuit court of appeals, tenth circuit.

Among other reasons for directing a verdict, the trial court was of the opinion that there was no substantial proof that death resulted from the workman's work. The proof was most unsatisfactory, said the circuit court of appeals. Conceding that death resulted from pneumoconiosis, the attending physician's opinion that it resulted from the work was formed, he testified, because he could find no other reason for it. However said the court, pneumoconiosis concededly results from deposits of foreign material, and Grammer did work in a dust-laden atmosphere. That the physicians who testified never knew of another still worker becoming so affected, and that the medical books contain reference to no other case, merely goes to the weight of the evidence. In the opinion of the appellate court, the evidence was sufficient to justify a submission of the question to the jury. If Grammer died of pneumoconiosis and if his occupation had anything to do with it, it was because of the dust in which he worked. He knew the dust was present when he took the job and he kept it year after year. He knew it was harmful to the lungs, for he was furnished with a respirator and told to wear it. While assuming the ordinary, known risks attendant on inhaling dust-laden air, he did not assume the risk of any concealed dangers lurking in the dust. The plaintiff contended that the presence of carbon monoxide and hydrogen sulphide in the stills contributed to the pneumoconiosis. Any finding by a jury, said the court, that hydrogen sulphide or carbon monoxide had anything to do with the pneumoconiosis would rest on speculation. There was nothing in the record to warrant a finding that, after the forced ventilation, there remained in the stills a sufficient amount of the gases to do injury. There was furthermore, no evidence of acute or chronic poisoning of still workers due to either gas.

The petroleum corporation continued the court, was engaged in the refining of oil a business attended with some danger as are nearly all constructive undertakings. Its equipment was standard and not defective. It followed the approved practices. It did all that was then known to minimize the risk to its employees. It operated year after year with no occupational disease resulting from the work. It had no reason to suspect any such. Tested by the principles of fault which underlie recovery for injuries at common law, concluded the court, we do not believe that the plaintiff has established her case. The judgment of the trial court was consequently affirmed.—*Grammer v. Mid-Continent Petroleum Corporation* 71 F. (2d) 38

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk () are abstracted below

Theory of Binocular Vision—Verhoeff states that corresponding retinal units are represented separately somewhere in the brain but that each of every pair is represented in consciousness by the same single unit. When this conscious unit receives the stimulus from one retinal unit it excludes the stimulus from the corresponding unit. For the process by which, in consciousness, stimuli from one eye are thus substituted for those from the other the term 'replacement' is suggested. The controlling factor in this process is attention. For individual retinal units replacement is always totally complete but for retinal images it may be complete or incomplete. Replacement cannot reverse the relation of a conscious image to its contiguous background unless this reversed relation already exists between one of the retinal images and its own background. For the seeing of two corresponding images as one the term 'unification' is suggested. True unification is accomplished by the complete or partial replacement in the conscious image of one retinal image by its corresponding image. When the two retinal images are nearly alike the conscious image has a nearly con-

stant value, which is nearly the same as that of each retinal image seen with one eye occluded. When the two retinal images differ in intensity or color, the attention and therefore the replacement may fluctuate (rivalry). So-called fusion of disparate retinal images does not occur but seems to occur when two similar disparate images produce the effect of depth and one of them disappears by replacement. It is suggested that this process be termed "quasi-unification." In the stereoscopic perception of depth, quasi-unification generally occurs, but depth perception is possible when both of any pair of disparate images are visible. Two disparate images, as projected on the horopter, appear about half the distance apart when seen stereoscopically as they do when seen in binocular simultaneous vision. When a disparate image disappears during stereopsis, the position of its fellow remains unchanged. Binocular luster is produced when, as the result of replacement, there is represented in a conscious area a mosaic consisting of units or minute areas of high intensity interspersed with areas of low intensity. It differs essentially from monocular luster only in the fact that it is inconstant. Since in stereoscopic vision one of each pair of disparate images can be and generally is invisible, since crossed images cannot be consciously distinguished from uncrossed disparate images and since binocular fixation can occur when one of the images fixed is invisible, it is evident that the process on which stereoscopic perception of depth depends cannot be recognized consciously. Since there is good reason to believe that corresponding retinal images are represented separately in the occipital lobes, it seems possible that the sensory nervous mechanism for stereoscopic perception of depth is situated chiefly in this region.

Ultraviolet Therapy of Gonococcal Cervicitis—Abramson treated fifty cases of gonococcal cervicitis with ultraviolet rays. The patients showed a profuse purulent cervical discharge with marked erosion and eversion of the lips of the cervix. In most cases an associated urethritis was present and three presented a bilateral Bartholin's cyst. The vagina and cervical canal were swabbed clean with cotton. A cotton applicator was placed in powdered Carica papaya and then carried to the cervical canal. Within twenty to forty seconds the mucus had been entirely digested and liquefied and the cervical canal was clean and could be treated properly. Following this cleansing the cervical canal and any erosions were painted with 10 per cent silver nitrate. The official applicator was then inserted into the canal to the internal os and treatment given. All cases were started with a minute and a half exposure. The length of time of the exposures was rapidly increased to ten minutes. An exposure of three minutes was just as effective clinically as the longer treatments, therefore treatments of a maximum of only three minutes were given. With few exceptions after four or five treatments the cervical smears became negative with no subsequent positive smears. The amount and character of the discharge rapidly changed from the profuse purulent type to normal. On returning for a checkup preliminary to discharge, all cases showed a normal cervical secretion at least three negative smears and no clinically suggestive signs. The effect of the ultraviolet irradiation was not as rapid in curing a marked and extensive erosion of the cervix as in stopping the discharge. Cases of erosion not healing after several ultraviolet treatments were treated by the Kimble-Jaros and Cherry techniques of cervical coagulation. In

every case treated the end result was healing of the lesion. Patients were treated twice weekly and the average number of treatments given was twenty. There were no ill effects from the treatment, although two of the cases showed a small amount of bleeding after each removal of the applicator. Four patients also complained of uterine cramps at various times during the treatment but these were not constant and did not affect the results. In comparing seventy patients who had been on the usual routine treatment it was found that the average case was treated twice weekly, and that the average length of treatment was eighteen months.

Massive Intravenous Injections.—Warthen states that large amounts of the usual solutions used for infusions may be injected intravenously into dogs without causing death or evidence of cardiac embarrassment. Injections of excessive amounts of fluid result in cerebral or pulmonary edema. The most favorable changes in the blood chemistry occur with infusions of isotonic solutions of dextrose and sodium chloride. A 5 per cent solution of dextrose causes slightly more desirable changes than does a 0.7 per cent solution of sodium chloride. Injections of hypertonic solutions of dextrose and sodium chloride cause distinctly unfavorable changes in the blood chemistry. The blood sugar value increases following infusions of 0.7 per cent sodium chloride solution and decreases following infusions of hypertonic sodium chloride solution. Large infusions of dextrose and of sodium chloride solutions cause little if any change in the fragility of the red blood cells. There is a marked acceleration of the pulse rate during intravenous infusions. The injection of fluids intravenously results in an initial rise in the arterial blood pressure. This is followed by a secondary fall to, or slightly below, the preinjection level during infusions of isotonic solutions. This secondary fall is diminished or absent during infusions of hypertonic solutions. There is a marked increase in the venous pressure during large intravenous infusions. Diuresis is most marked following infusions of 5 per cent dextrose solution. Edema of the subcutaneous tissues does not occur following the rapid injection of large amounts of fluid intravenously. Edema of the wall of the stomach and of the intestine associated with fluid in the gastro-intestinal tract and in the peritoneal cavity does occur following large intravenous infusions. The intravenous injection of 10 per cent dextrose solution results in frequent fatalities in dogs.

Primary Isolated Lymphogranulomatosis of Stomach.—Comando points out that Hodgkin's disease may originate in the lymphoid tissue of the gastro-intestinal tract and remain as a localized tumor for some time. The diagnosis usually made is that of carcinoma. Before the days when gastric resection was the operation of choice for gastric tumors and for infiltrating gastric ulcers, virtually no cases similar to the one the author

describes were reported in the literature. This type of gastric lesion is a distinct clinical entity, and the favorable results that have followed operative treatment in several cases more than justify the radical operation. The pathologic changes noted in his case were those of an infiltration of the distal portion of the pars media and the proximal part of the pyloric portion of the stomach. A Wassermann test was advised in order to rule out syphilis before an interpretation of the condition as a malignant process was accepted. An increased density was noted in the region of the liver. A small deposit was noted in the lower lobe of the left lung. The patient left the operating room in good condition and made an uneventful recovery. In two months he had gained 25 pounds (11.3 Kg.), had returned to his usual occupation and was able to eat all kinds of food. A careful follow up has shown no evidence of any recurrence and the patient continues to feel well.

Epithelioma Following Avulsion of Scalp.—Burns describes the late onset of fatal complications and their character following avulsion of the scalp. The sequence of events was (1) spontaneous epithelization over a period of sixteen years, (2) subsequent ulceration and infection of a portion of the healed area during pregnancy, (3) development of osteomyelitis of the skull, which later necessitated removal of the top of the calvarium, (4) failure in attempts at plastic repair, and (5) death with symptoms of meningitis twenty-one years after the accident. At the time of necropsy, direct growth of tumor cells across the meninges and through the brain substance was established. From the histologic study it seems probable that these cells preceded and marked the path of infection which developed later. The external irritating agencies played the most important part in producing a malignant tumor.

Complete Nephro-Ureterectomy.—Colston outlines a simplified technic by which complete nephro-ureterectomy can be accomplished, avoiding the technical difficulties and postoperative complications that may occur when a cuff of mucous membrane about the ureteral orifice is excised. The operation is indicated in the treatment of primary tumors of the ureter and papillary tumors of the pelvis of the kidney. In many cases of renal tuberculosis in addition to nephrectomy, there is also a definite indication for ureterectomy. The extent of the tuberculous process in the ureter can best be determined by a study of the ureterogram. Alternate areas of constriction and dilata-

tation with a "moth eaten" appearance of the edges of the pyelographic medium in the ureter provide sufficient evidence to diagnose an extensive ulcerative tuberculous ureteritis. In such cases excision of the ureter is definitely indicated. The operation of nephro-ureterectomy or ureteronephrectomy entails little more shock to the patient than a simple nephrectomy. Three cases presenting different pathologic conditions are reported. Previous to the operation the bladder is distended with sterile water. The anesthesia may be chosen according to the surgeon's preference. The usual incision is made commencing in the costal angle and extending down below the twelfth rib for a variable distance depending on the necessity of the case. The muscles are divided, the deep fascia is opened and divided up to and including the costovertebral ligament. The kidney is separated from adhesions and the pelvis and ureter are dissected free, the separation of the latter structure being carried down to the brim of the bony pelvis. The vascular pedicle is isolated and controlled with three clamps. The kidney is excised and the vascular stumps are tied twice with chromic catgut. The kidney is replaced in the wound which is packed with gauze. The patient is then turned to a prone position with the head somewhat depressed and tilted on the table away from the side of operation. An incision is made parallel with Poupart's ligament, the muscles are divided in the line of their fibers, the peritoneum is pushed toward the midline and the ureter is picked up and separated from the retroperitoneal structures. The ureter is completely separated from all structures down to its entry in the bladder. It is clamped twice just above the bladder and divided with the electric cautery. The exposed ureteral mucosa of each stump is thoroughly and completely destroyed by the electrocautery; the proximal stump is tied with catgut and the clamp is removed. The distal stump of the ureter is grasped by its wall on each side, the clamps being placed in such a manner as not to occlude the lumen. The occluding clamp is removed. A coagulating electrode with a bulbous end of about 10 mm. is introduced into the ureteral lumen and passed slowly back and forth through the lumen with an appropriate current strength until the entire mucosa of the ureter has been destroyed. The distal stump is ligated and the wound is closed in layers with tube drainage. The patient is replaced in the nephrectomy position and by gentle traction and blunt dissection the ligated proximal stump is drawn up and the kidney and ureter are removed intact. The nephrectomy incision is closed in layers with drainage.

Methylene Blue in Treatment of Urinary Tuberculosis

—The studies of Greenberg and his associates indicate that the impurities in methylene blue are responsible for the untoward symptoms produced when the drug is used in urinary tuberculosis, thus demonstrating that the blue dye is present as in the spontaneously colored kidneys but in the nonblue form and that the production of a pure drug is essential. Through the work of Armstrong the authors are now provided with an almost perfectly pure product. They have used this in four cases. It has produced no irritating symptoms and the cases show improvement as in the cases which benefited by the commercial product when tolerated. Whatever benefit results from the use of methylene blue should be ascribed to the dye and not to its impurities. A method has been devised for the preparation of pure methylene blue.

Hydrostatic Ionization of Nose—Gale uses the following technique. The patient is seated with the head slightly inclined forward. The nasal tip of a glass tube about $7\frac{1}{2}$ inches long with a sealed in electrode at the base of the tube is inserted

into one nostril, sufficiently snug to prevent leakage. The positive pole of the galvanic apparatus is connected with the sealed in electrode, while the patient holds in one hand a moistened pad connected with the negative electrode. The top of the tube is funnel shaped and through it the ionizing solution (1 per cent zinc sulphate) is slowly poured. Since the top of the glass tube is above the level of the nose, the solution in the nose will rise to the same level it occupies in the tube. In this way the entire nasal cavity will be flooded. As the fluid touches the nasopharynx, the soft palate is automatically raised and the solution begins to escape from the opposite nostril. At this point the patient occludes the opposite nostril, and the entire nose is filled with ionizing solution and ionization is already taking place, as electrical contact has been made. The patient holds the mouth open and breathes deeply. There will be some slight escape of solution from the throat, which is readily made up by pouring more solution into the funnel to keep it at the proper level. The duration of treatment is from ten to twenty minutes, and from 6 to 10 milliamperes of current is used. The author's results obtained in allergic conditions of the nose and chronic catarrhs have been good.

Experimental Production of Fat Necrosis—Neal and Ellis produced experimental fat necrosis by the injection of commercial pancreatins pancreatic secretions from dogs and purified and concentrated lipase fractions derived from animal and vegetable sources. The various lipase fractions possessed physical and chemical properties characteristic of enzymes in that they were not thermostable; they were inactivated by ethyl alcohol in strengths above 50 per cent, strong acids and strong alkalis, and they decomposed ethyl butyrate. The highly purified fractions were colloidal in character and were globulin-like. The lipase containing fractions showed no species specificity for animals in their ability to produce fat necrosis, as evidenced by the fact that the lesion has been experimentally produced in vertebrates (fish, turtles, birds and mammals) in which the body temperatures ranged from 18 to 43°C (64.4 to 109.4°F). Clinical fat necrosis goes through a normal process of repair and is not a fatal lesion, but the condition that precedes it and is responsible for it is often fatal. The presence of fat necrosis in the intra-abdominal fat or in wounds of the abdominal wall indicates a damage either to the pancreas or to a pancreatic duct. The fat necrosis then is a secondary and not a primary lesion. In experimental animals all stages of the lesion up to complete repair have been found. In the human subject at necropsy or in cases in which a second surgical procedure is necessary within the abdominal cavity after fat necrosis had been observed at a previous operation

one may find repair even to a complete disappearance of such previous areas. In the experimental work the authors used every reasonable animal and chemical control to prove that they were dealing with a purified lipase fraction and that the various extractives employed were not capable in themselves of producing these changes. Injections of the extractives of p_n values even beyond the ranges employed have failed to produce the condition. Histologic examinations of all material were done, irrespective of the gross observations, as a means of eliminating false interpretations, such as postmortem changes, and to prove that pancreatic lesions were not responsible for the changes.

Report of Three Years Clinical Study of Scarlet Fever Immunization Emily P Bacon Philadelphia —p 331

Treatment of Prenatal Syphilis with Acetarsone — Pillsbury and Perlman used acetarsone in the treatment of seventy-three cases of prenatal syphilis, no other form of syphilotherapy being given in forty-four. Treatment in a considerable proportion of these cases is not yet completed. The clinical response seems excellent and the initial influence of the drug on the serologic condition of the incompletely treated patients is regarded as satisfactory. Acetarsone has a definite tendency to produce reactions of varied types, some of which may be serious. The advantage of early diagnosis is apparent in the better serologic response in patients less than 1 year of age. Testing of the urine for arsenic may or may not prove a feasible method of control in patients in whom it is suspected that the administration of treatment is being neglected. Acetarsone therapy demands the closest type of observation and control. The following precautions and methods are essential: (1) complete preliminary examination of the patient, including urinalysis, (2) an extremely cautious and reduced dosage level in infants, in patients with the slightest urinary abnormalities and in those who have had previous reactions to the drug, (3) weekly observation and urinalysis, and (4) permanent cessation of acetarsone therapy with the occurrence of any severe reaction. The method deserves continued clinical trial and cannot be regarded as completely evaluated, as (1) adequate information of final results on the basis of five or ten year follow ups is not available, (2) the necessary dosage level is still a subject of considerable dispute, (3) the advisability or necessity of combining it with some type of heavy metal therapy has not been determined, and (4) the drug has a definite tendency to produce reactions, the variety of which is apparently increasing.

**Control of Bronchial Asthma* N F Shambaugh and S M Alter Los Angeles —p 210

Control of Bronchial Asthma —Shambaugh and Alter prevented the attacks of paroxysmal dyspnea in fifty cases of bronchial asthma by a regimen based on elimination, by postural drainage, of the accompanying bronchial and pulmonary exudate. The first therapeutic step is reduction of the viscosity of the bronchial and pulmonary exudate in order to facilitate its evacuation. Then the patient is instructed to kneel on a chair or stool and place both hands on the floor. The more nearly the thorax approximates an inverted vertical position, the more nearly ideal are the results. While in this position the patient coughs as nearly continuously as possible and peroral drainage of the exudate is thus accomplished through the combined agencies of the tussive squeeze,iliary drainage and the bechic blast. The exudate is then expectorated. The inverted position is maintained for a minimum of three minutes, regardless of productivity. This procedure is carried out at least twice daily, preferably on arising and retiring. Coughing during the interval between drainage procedures is the signal that insufficient evacuation of the bronchial passages has been accomplished. Although it is possible by the foregoing procedure to prevent asthmatic attacks when active infectious foci are present, total and permanent quiescence of the bronchial and peribronchial inflammation will occur only after ablation of these foci. Some of the authors' patients have been asymptomatic for four years without treatment. Their series consists of a group of severe and recalcitrant cases between the ages of 6 and 75 years. Strict adherence to the regimen has not yet failed to keep the patients free from asthmatic attacks.

Phagedenic Ulceration—Holman presents four cases exhibiting the characteristic features of progressive and relentless bacterial ulceration of the skin and subcutaneous tissues. The inference is that some intestinal organism or organisms are in some way responsible for these infections. In the four cases reported one followed an appendectomy, two followed the draining of axillary abscesses secondary to lesions of the hand—one incurred while handling animal fertilizer the other while grating carrots—and the fourth occurred in a plumber whose clothes were habitually soiled by sewage. In these cases two organisms were invariably found the streptococcus recovered was hemolytic and aerobic. The authors' animal experiments with attempts to reproduce the lesion by inoculation of two organisms singly and in combination corroborate Meleney's observation that two organisms together produce more pronounced lesions than single organisms but in no instance was he or Meleney able to reproduce the progressive lesion seen in the human cases. In studying the factor of individual resistance a basal metabolic rate of minus 23 and minus 25 per cent was observed in the fourth case. The third patient when on the road to recovery, showed a normal metabolic rate of plus 7 per cent. In treating such infections, every effort should be made to increase the resistance of the host to infection. This may be accomplished by transfusions, sun baths and a high vitamin diet, augmented by cod liver oil and vitamin B. The case of Probst and Seelig responded promptly and decisively to blood transfusion from immunized donors. Locally, the resistance of the host to the infecting organisms was affected in the axillary abscesses by the introduction of maggots. In adopting maggot therapy adequate medication, such as morphine, pantopon or sodium amylal, should be employed every two hours to control pain and the maggots must be used in sufficient number so that every part of the wound is being attacked simultaneously. The success of the debridement lies in carrying the incision through absolutely healthy skin and subcutaneous tissues, and abolishing all pockets in which pus may accumulate and stagnate. All overhanging tissue must be removed. On the first admission of the second patient, in the presence of an advanced infection the white cells numbered 15,550 polymorphonuclears 82 per cent banded 47 per cent and segmented 35 per cent. Eleven days later, four days after an extensive debridement the white cells numbered 12,000 polymorphonuclears 82 per cent banded 70 per cent, segmented 12 per cent. Thirteen days later, when the suppuration was under better control, the white cells numbered 9,100 polymorphonuclears 64 per cent banded 17 per cent segmented 46 per cent. The author states that it seems unlikely, from the fatal outcome in this case, that the deep seated axillary abscesses in the first and third cases could have been successfully treated without recourse to maggot therapy. Complete cautery debridement and the abolition of all pockets was obviously impossible. Only maggots could cope with the dirty edematous granulation tissue, containing numerous organ-

isms, which extended in each instance to the very apex of the axilla. One unexpected advantage resulting from the maggot therapy was the healing that occurred in both axillary abscesses without permanent cicatricial contractures. Full range of motion is now present in both cases. In treating axillary abscesses it is important to support the arm in the abducted position by means of the Balkan frame.

Repair of Defects Resulting from Full Thickness Loss of Skin from Burns—Brown and Blair outline the essential points of care that have usually proved of benefit for patients in whom a large area of the full thickness of the skin has been destroyed by a burn. 1 The patient should be kept free from pain and from objectionable restraints, sedatives should be used carefully, and interest in the surroundings should be developed. Nutrition must be kept up and transfusions may be required frequently. 2 The local care of the open wounds has for its object the cleaning up of the areas. Surgical drainage is best accomplished by the use of sodium chloride dressings or by the continual sodium chloride bath for from one to three hours a day followed by dry heat or further wet dressings. Many antiseptics (common and proprietary) and gentian violet have been used, but at present the authors rely on surgical solution of chlorinated soda if anything other than sodium chloride is necessary. 3 If large areas are to be covered it is necessary to develop a method of obtaining free skin grafts of suitable thickness in large amounts, cutting them rapidly and ensuring prompt healing of the area from which the grafts are taken. The graft (thick split) that they have found most applicable over open wounds is one that includes from one half to three fourths of the thickness of the skin. 4 The care of the grafted area requires a simplified method of applying a pressure dressing and of keeping it moist if necessary. i. e., when there is reason to fear a degree of infection that might damage the graft, a wet sodium chloride dressing with irrigation tubes incorporated in it is put on and pressure is obtained over the area with sea sponges bound on firmly with heavy gauze rolls. The dressings are kept constantly moist for four days, at which time the first dressing is changed. If the area is quite free from contamination, a sponge pressure dressing is applied with a few layers of grease gauze over the graft. 5 In the repair of late burn contractures, free skin grafts can be used extensively and give permanent bearing surfaces in many instances. They often may be substituted for a tedious, laborious use of pedicle flaps that require multiple operations. If there are sinuses extending down into scar folds that harbor organisms detrimental to the chance of a skin graft taking, a preliminary opening is done and sometimes a huge open wound is produced. In the grafting of all contaminated open wounds, the thick split graft is used rather than a full thickness graft because of the greater assurance of its taking in such a field. If the late contraction is healed so that a clean operation can be done, the use of a full thickness graft can be undertaken much more safely, but even here the split graft can be used satisfactorily and may even be required if the area to be grafted is so large that the necessary amount of full-thickness skin cannot be sacrificed. 6 Burns of the hands deserve special attention in order to prevent deep infection, which rapidly fixes the tendons and joints and produces deformities that may never be overcome. For deep losses, the first treatment should be active surgical drainage, active movement should be encouraged, the fingers should be dressed apart, and the whole hand should be kept in a position of function. The average burn should be ready for grafting in three weeks, if tendons have not been exposed. 7 The rehabilitation of the patient's activities should be started early if possible even before surgical restoration is started. In all the working contacts with patients, a firmness of purpose should be maintained that will tend to keep the patient's morale on the highest possible level.

The Esophagus—In addition to pointing out that fibrosis of the esophagus, especially of the terminal portion, is the result of infection from contiguous organs, Mosher shows that fibrosis of isolated areas is fairly common, especially in such chronic infections as arteriosclerosis. In infections of the blood stream, the esophagus is often involved to the extent of ulceration. In acute infections (pneumonia) the esophagus may be infected. Chronic infection as shown by an infiltration of

lymphocytes under the epithelium and in the glands and about the gland ducts, is also common. Dilatation of the subepithelial blood vessels is an almost invariable occurrence in diseases, such as cirrhosis of the liver, which impede the venous circulation. Cirrhosis of the liver and infection of the gall-bladder are among the chief causes of infection of the esophagus. As necropsy specimens of these conditions accumulate, this fact is becoming more and more evident. Hemorrhage into the muscular layers extensive enough to disrupt them may occur when there is back pressure on the esophageal vessels. The glands of the esophagus are especially liable to infection and are probably the chief route by which the esophagus is infected from within. One form of solitary follicle is simply a collection of lymphocytes following a gland duct to the surface. The esophagus can be infected from within and from without and is often infected in both acute and chronic disease. In the esophagus, fibrosis follows infection, as it does in other organs of the body. As the esophagus is so frequently infected, there is abundant cause for strictures or fibrosis to occur in any part.

Artificial Rupture of Membranes as Means of Inducing Labor—Rucker believes that rupture of the membranes is an efficient means of inducing labor at term and a useful method in certain cases of marginal placenta praevia and toxemias of pregnancy. With a proper technic there seems to be less risk of infection than in uncomplicated spontaneous labors. Apparently there is some risk of a contraction ring developing. The risk to the baby is not great. There is a small chance of the cord prolapsing, especially if the presenting part is not engaged.

Etiology of Vascular Symptoms of Cervical Rib—Blair and his co-workers examined histologically the brachial plexus from a case of cervical rib in which the vascular affects were pronounced. They agree with the view of Telford and Stopford that the clinical picture in these cases is one of irritation of the sympathetic (vasoconstrictor) fibers passing to the distal arteries of the upper limb, and not one of paralysis of sympathetic fibers, as other observers thought. In their case the rapid return of pulsation in the radial, ulnar and brachial arteries after operation signifies that thrombosis had not supervened on the arterial spasm. The increased tension of the arterial walls and the diminution of their lumen had alone been sufficient to render pulsation undetectable. That pulsation in these arteries however, did not return immediately to normal on removal of the cervical rib and the incomplete disappearance of pain after this operation suggest that the irritation of the sympathetic fibers is not due merely to mechanical pressure of the rib but that a chronic aseptic inflammatory lesion in the nerves immediately related to the rib is produced by the pressure irritation. The thickening of the endoneurium and the proliferation of endoneurial nuclei observed by the authors in the lower trunk of the brachial plexus (particularly in its inferior part) and in the distal part of the first dorsal nerve, where it came into immediate relation with the cervical rib, appear to them to be of special significance. They interpret these histologic observations as evidence of irritation by the rib in the immediately related nerves. The collection of nerve fibers (largely unmyelinated) which, for a distance of one fourth inch had a separate existence in the inferior part of the lower trunk of the plexus, cannot be considered an unjoined ramus as Telford and Stopford claim for the separate bundle of unmyelinated fibers. In the present specimen the number of unmyelinated fibers in this collection forms only an extremely small fraction of the total number of unmyelinated fibers in the lower trunk of the plexus, and it is difficult to believe that irritation of these few unmyelinated fibers can be responsible for such widespread arterial spasm as was present. The fact that only the lower trunk and the first dorsal nerve showed

histologic evidence of proliferation of endoneurium and endoneurial nuclei and the authors' interpretation that this lesion was responsible for the widespread irritative effects on the sympathetic vasoconstrictor fibers to the vessels of the limb implies that a large proportion of the vasoconstrictor unmyelinated fibers enter the limb by way of the lower trunk or that these fibers in the lower trunk of the plexus have a particularly widespread distribution to the arteries of the limb. Unmyelinated fibers in general are more numerous in the lower trunk. The authors are unable to give any information as to whether the nerves on the under aspect of the subclavian artery, derived from the sympathetic chain and from the ansa subclavia were in any way affected. The lesion affected principally the unmyelinated vasoconstrictor fibers in the inferior part of the plexus. There was no anatomic segregation of the unmyelinated fibers which would explain their special involvement. It is desirable that operative treatment, whether removal of the cervical rib or division of the scalenus anterior muscle allowing the rib to droop, should be undertaken as early as possible to relieve the plexus from harmful pressure.

Renal-Adrenal Adherence—In the course of the routine performance of approximately 1,500 postmortem examinations Davie has on six occasions observed a degree of bilateral renal adrenal adherence which would have rendered impossible the removal of the kidney without the coincident removal or serious laceration, of the adrenal. In all these cases (adults) the small amount of loose connective and fatty tissue that usually separates the anterosuperior surface of the kidney from the postero-inferior aspect of the superposed adrenal was absent in whole or in part. In some of the cases the lower portion of the adrenal was thinned out and applied closely to the upper third of the anterior surface of the kidney and section showed either complete absence of any capsular connective tissue between the two organs or else the presence of only a single attenuated layer of fibrous tissue separating the two organs and serving as a capsule for both. No other forms of developmental abnormalities were present. In particular, in none were there macroscopic evidences of adrenal rests within the renal parenchyma nor were any of these rests discovered in the considerable number of sections cut for histologic examination. No ectopic adrenal fragments were found.

Interstitial Radium Treatment of Carcinoma of Breast—Hutchinson describes an interstitial radium technic for carcinoma of the breast that he believes is sound in principle, safe in practice and is claimed to be a radical radium implantation, the main features of which are the following. According to the size of the breast one or more layers of needles are inserted from the medial and lateral sides, in such a way that the needles of the deepest layer, undercutting the breast do not meet in the center and that any subsequent more superficial layers approximate gradually more closely until the effect achieved is that of a cone of radioactive foci with a central zone adequately irradiated but not containing actual needles. The peripheral ends of the needles are crossed at the base of the cone, and occasionally in the subareolar area one or more needles are inserted at an angle of 90 degrees to the deeper planes to close the apex of the cone. Such peripheralization of radium foci avoids the high central intensity falling rapidly toward the periphery, inevitable when any volume of tissue is implanted in a uniform or in a cartwheel manner. The needles used are of a content of 3 mg, active length 4.5 cm, screened by 0.5 mm of platinum and of 2 mg, active length 3 cm with similar filtration. The technic is also given for the irradiation of tumors of the axilla, supraclavicular area and mediastinum. Stereoscopic roentgenograms bear out the contention that it is possible to irradiate the breast and its lymphatic areas in a satisfactory manner. The needles are left in position for seven days as a rule. As experience of distribution of radium foci and of total dosage accumulates, complete disappearance not only of the tumor mass but also of glandular deposits becomes more and more frequent. There appears to be an optimal dosage at which even the largest primary and secondary masses provided the tumors are of the sensitive type, undergo complete resolution leaving no trace of their presence. The radical technic, as described, has been employed only throughout 1933. It is therefore not possible to speak of its results from a statistical standpoint. The immediate results however are encourag-

ing. The proportion of cases in which disappearance of the primary growth and of its secondaries takes place without leaving any palpable residue is definitely increasing. Up to October 1933 the method was used in twenty-three cases, fourteen of the patients are alive and well, six are alive with evidence of disease, which may yet be amenable to further treatment, and three are dead.

Concentrated Liver Extract for Parenteral Administration in Pernicious Anemia—Scowen and Spence used a liver extract in six patients having pernicious anemia which overcomes the disadvantages of cost and frequent injection. The preparation is a protein free aqueous extract of liver, 1 cc. being extracted from 25 Gm. of liver and equivalent in activity from thirty to 100 times this weight of fresh liver by mouth. Only one intramuscular injection of from 5 to 10 cc. is necessary to bring about marked clinical improvement and to raise the blood count to the normal level. Maintenance doses of 5 cc. are required only at intervals of one or two months. On the third or fourth day after the initial injection the patients experienced a return of strength and a sense of well being. This often preceded, but sometimes coincided with, the beginning of the reticulocyte response. Reticulocytosis usually started on the third or fourth day and rose to a maximum on the fifth or sixth. In three cases the maximal response did not rise above 15 per cent. The degree of reticulocytosis bore no relation to the eventual rise of red cells. A reticulocyte rise was not observed after subsequent injections. If the initial dose of the liver extract was adequate the red cells and hemoglobin increased steadily after a single injection to reach a normal figure in four or five weeks. Two patients however who received an initial dose of 5 cc. failed to touch a normal level until a second dose was given. As a rule an initial dose of 8 cc. of the preparation appears to be adequate, but in severe cases a dose of 10 cc. is desirable. The interval between maintenance doses varies not only from patient to patient but in each individual from time to time. A blood count should be done every two weeks and any indication of a fall calls for a further injection.

- *Heredity in Cancer and Its Value as an Aid in Early Diagnosis Madge Thirlow Macklin—p. 49
Studies in the Nephrotic Syndrome D. M. Lyon and D. M. Dunlop—p. 68

Heredity in Cancer—Macklin asserts that cancer (covering all tumors, benign or malignant) is due to an inherited factor in other words it is hereditary. One cannot say that it is a mere predisposition that is inherited, for that means that a precipitating cause must always be present, and there are numerous records in which there is no evidence of a precipitating cause. Cancer cannot be ascribed to chronic irritation as the sole cause, for such injury is not always followed by cancer and cancer is not always preceded by such injury. Cancer is not an entity any more than infectious diseases are an entity. Cancer of a specific type in a specific organ at a specific age tends to occur in families. When viewed in this light, it is evident that cancer is not so frequent that it is to be expected in several members of a family on the basis of chance alone. In a series of families selected merely because two members in the family had died of the same type of tumor the author observed that related persons were affected ten times as often as unrelated persons. Related persons were represented by parents and children or by brothers and sisters. Unrelated persons were represented by husband and wife. The latter class

exemplify the number of times one might expect two people in a family to be affected if cancer were due to chance alone. Chronic irritation when present appears to play a part in accentuating the speed of a reaction that was destined to occur at a later date. Sometimes the reaction would have been so long delayed past the normal span of life that the chronic irritation assumes the part of the sole etiologic agent, for practical purposes. In other cases it plays no part whatever. Identical twins who have the same type of tumor in the same organ and frequently at the same age afford excellent proof of the part that inheritance plays in the production of cancer. Belief in the inheritance of cancer offers opportunity for early diagnosis. No one patient can be periodically examined for all the types of tumor that may occur. They can be examined periodically for the type or types of tumor that are most common to the other members of their family.

Postural Hypotension.—Croll and Duthie state that while only eighteen cases of postural hypotension have been recorded, many cases may have escaped detection through failure to ascertain the blood pressure in the erect as well as in the supine posture. Giddiness on suddenly assuming the standing from the sitting or recumbent position is not uncommon and may be due to the curious failure of the blood pressure to adjust itself to the altered position found in postural hypotension. The authors present the case of a man, aged 37, otherwise apparently normal from the cardiovascular standpoint, whose blood pressure showed remarkable variations with change of posture, a marked fall of pressure accompanied by giddiness invariably taking place when the patient changed from the supine to the standing posture. The fall of pressure was associated with a decrease in the water excretory function of the kidneys. The pulse rate showed a normal response to the change of posture. Abdominal compression, the application of tourniquets round the limbs and the administration of epinephrine, solution of pituitary and histamine alike failed to prevent the fall of pressure taking place.

Trichomonas Vaginalis in Vaginitis.—Bykhovskiy and Gouchansky found trichomonas in 52 per cent of their patients who had purulent vaginitis. Trichomonas vaginitis shows a typical clinical picture but may sometimes simulate gonorrhea. It is characterized by a chronic course and a tendency to relapse. According to their observations, the most stable results are obtained by applying a combined treatment of mercuric chloride and lactic acid and prolonging the duration of treatment. Symbiosis of trichomonas and gonococci is common and must always be considered a possibility. In such cases antitrichomonas therapy aggravates the course of the gonococcal process. They believe that at least one if not the only method of infection is by coitus. The cases definitely of this origin confirm the pathogenic power of trichomonas.

Operation of Crural Hernia by Inguinal Route. Late Results. B. Herzberg—p. 91

Hypercholesterolemia in Pathogenesis of Hepatic Calculi.—Giuliani says that excess of cholesterol in the bile of the gallbladder is the determining factor of cholelithiasis. His statement is supported by chemical, clinicochemical and experimental research. The concentration of cholesterol in the bile of the strawberry gallbladders, removed by cholecystectomy and chemically studied by the author, reached 8 per thousand and 11 per thousand, respectively, in comparison with the normal concentration. The concentration of cholesterol in the bile, obtained by duodenal sounding six or seven years after cholecystectomy in the same patients, reached only 1 per thousand. Experimental stasis of the gallbladder was produced in dogs by means of fixation of the gallbladder to the duodenum. It resulted in the development of a strawberry gallbladder, formation of calculi and increase of the cholesterol in the bile of the gallbladder. The formation of calculi, the development of a strawberry gallbladder and hypercholesterolemia were obtained in dogs by the introduction of culture broth of colon bacillus in the gallbladder, both when the organ was left in its place and when, after the introduction of the broth, it was fixed to the duodenum. The author concludes that biliary stasis and infection are the local causal factors of hypercholesterolemia in which the strawberry gallbladder and cholelithiasis originate, and that cholecystectomy is the proper treatment of cholecystitis with or without calculi.

*Biliary Giardiasis A. Balena—p. 47

Biliary Giardiasis.—Balena discusses the role of Giardia intestinalis in the pathology of the biliary tract. His studies are based on the observation of nineteen cases. He regards Giardia intestinalis as the direct agent of the inflammation of the gallbladder commonly associated with the infestation. The author describes three clinical forms of biliary giardiasis: (1) the gastropastic form, characterized by cramps of the stomach and by clinical and objective symptoms similar to those of duodenal ulcer, (2) the pseudolithiasic form, which includes the pseudocholelithiasic and the pseudonephrolithiasic types, and (3) the cardiac form, which includes the arrhythmic and the anginal types. The different syndromes produced by the infestation originate in a chronic catarrhal cholecystitis of the simple or the exfoliative type. The most frequent complications of the infestation are hepatic cholangitis, secondary to chronic cholecystitis and suppurative cholecystitis caused by pyogenic associated bacteria. As the infestation has been found only among persons living in certain rural centers it is advisable

to examine the feces periodically, after the administration of an alkaline purgative, for the detection of carriers who should be isolated and treated. The treatment consists in draining the duodenum and the cholecystic bile, after which intravenous injections of neosphenamine are given. This treatment is given at intervals of one week but is discontinued after the parasite in the bile has completely disappeared. To prevent a recurrence, it is advisable to give the patient one or two tablets of acetarsone on an empty stomach in the morning for several months. The tablets are given for five consecutive days, with intervals of three days of rest. By this treatment the permanent disappearance of the parasite from the bile is obtained.

Prensa Medica Argentina, Buenos Aires

22: 359-408 (Feb 20) 1935

- *Connective Tissue Tumors of Giant Cell Type F R Ruiz and E. A. Rossi—p 359
Acute Neuralgia of Infectious Origin Cases T Malamud B Jussem and I Ayler—p 392
Mesoscuritis of Azygos Lobulus A J Rey and J C Rey—p 401

Connective Tissue Tumors of Giant Cell Type—Ruiz and Rossi say that connective tissue tumors of the giant cell type are relatively benign, do not give metastasis and, if properly removed, do not recur. Their recidivation is slightly more frequent than that of benign tumors. They should not be designated as sarcomas, because the latter are often highly malignant while the former are not. The designation of gigantocellular sarcomas is preferable. Gigantocellular sarcomas may complicate a preexisting fibrous osteitis. The stroma is of typical fibroblastic cells, and in certain cases of irritability it changes to a hemangio-endotheliomatous type. The giant cells of these tumors are plasmodia sui generis with the typical characteristics of the giant cell of reaction against foreign bodies. They are entirely different from myeloplaxes and osteoclasts, on the one hand, and from the large cells (improperly called giant cells) of true sarcoma, on the other. They originate in the coalescence of endothelial cells, do not form vessels and constitute the limits of lacunar spaces. The tumors are highly vascular, with a predominance of the lacunar over the capillary vascularization. There are frequent foci of hemorrhages and of hematic pigments. Predisposition and trauma seem to be the etiologic factors. The characteristics of the giant cells and stroma of these tumors seem to indicate their inflammatory origin.

Temporary Disturbances of Cardiac Conduction (Partial Auriculoventricular Block) L Spreng—p 209
*Sensitivity to Epinephrine and Valvular Lesions D Gross—p 219

Spontaneous Hypoglycemia as Transitory Symptom—Unverricht states that patients with spontaneous hypoglycemia often show no organic changes. In the hope of detecting a definite syndrome that would permit the diagnosis of spontaneous hypoglycemia in general practice, he subjected patients with spontaneous hypoglycemia to dextrose tolerance tests, to starvation and to physical exertion. He detected varying symptoms but a definite syndrome could not be found. The only manifestation that all had in common was a feeling of weakness and somnolence. They were easily fatigued, had a deficient concentration capacity, felt depressed and complained of pressure in the head, flatulence, excessive sweating, eructation, vascular spasms, oppression of the heart, irritability, spasm in the region of the gallbladder and hyperacidity. The patients presented one or several of these symptoms. An unprepared examination of the blood sugar generally revealed nothing abnormal, but after a twelve or twenty-four hour fast, after a dextrose tolerance test or after physical exertions, great reductions in the blood sugar became evident and occasionally tremor, chills, excessive perspiration and accelerated pulsation developed. All these patients with transitory hypoglycemia had the urge to eat frequently and showed a preference for sweets and alcohol. The origin of transitory hypoglycemia is not clearly understood as

yet, but on the basis of its manifestations the author is inclined to believe that it results from a disturbance in the correlation of the various endocrine and nervous factors. The chief cause is probably an increased excretion of insulin, which in turn is caused either by disease of the islands of Langerhans or by their irritation by extra-insular factors. In three cases observed by the author, the spontaneous hypoglycemia represented a phase of prediabetes, because the loss of equilibrium in the carbohydrate metabolism resulted in fluctuations toward both sides. He observed also that some cases of hypoglycemia are caused by hepatic disturbances, but not all patients had disorders of the liver.

Sensitivity to Epinephrine and Valvular Lesions—

Gross determined alterations in the equilibrium of the sympathetic nervous system in patients with valvular lesions of the heart by testing the sensitivity for epinephrine. He observed sympathicotonia in valvular insufficiency and vagotonia in valvular stenoses.

Fractures of the Femur—Von Brücke reports the results obtained in 327 cases of fracture of the femur treated between 1922 and 1931 in the surgical clinic of Egon Ranzi in Vienna. Of these, 12 per cent were pathologic fractures. In one case of osteitis fibrosa cystica generalisata, fracture of both femurs healed on the removal of an adenoma of a parathyroid gland. The predisposition to the pathologic fractures of the area immediately below the lesser trochanter was demonstrated experimentally to be due to the fact that this area constitutes the weakest part of the femur. The treatment consisted mainly of extension with secondary manual reduction of the fragments. Operation was performed in 25 per cent of the cases. In recent years the operative treatment as well as the primary plaster cast has been given up more and more in favor of the extension method of treatment. The mortality amounted to 138 per cent. Only one case of pseudarthrosis was observed in a woman, aged 80. The results of treatment were excellent or satisfactory in 90 per cent and unsatisfactory or bad in 10 per cent. The average shortening of the limb amounted to 0.87 cm and the average flexion of the knee to 54 degrees. The author considers the primary plaster cast and the operative intervention the principal causes of bad results. The principal difficulty in the treatment is the avoidance of injury to the knee joint. Such injuries are caused not so much by the extension as by the plaster-cast immobilization. To prevent limitations of movements of the knee joint the author recommends that the extension be kept up as long as possible and that the knee be handled with the greatest care on the removal of the cast.

- Red Blood Picture in Diseases of Liver B Malamos—p 209
*Practicability of Gastrography in Diagnosis E Kolta and A Scholtz—p 224
Gallstone Formation Before the Age of 30 G Lemmel—p 262
*Vomiting of Blood in Organic Diseases of Nerves G Bodechtel—p 263
*How to Explain the Rapid Course of Acute Endocarditis Caused by Streptococcus Viridans Compared to Endocarditis Lenta Gertrude Schwalbe—p 283

Gastrography in Diagnosis—Kolta and Scholtz were able to demonstrate by means of gastrography that in diseases of the biliary tract the gastric contractions increase following the ingestion of butter, while in other disturbances, such as ulcer and catarrh the movements of the stomach cease entirely. This is helpful in the differentiation of the two groups of disorders.

Vomiting of Blood in Organic Diseases of Nerves—Bodechtel points out that a report by Cushing in which the author calls attention to the appearance of peritoneal symptoms

following operations for cerebellar tumors and the necroptic detection of new and perforated gastric ulcers in such patients, directed his attention to similar cases observed by him. After pointing out that Russian authors made similar observations on the basis of animal experiments conducted in 1923 (entirely independent of Cushing's studies), Bodechtel gives the histories of a number of cases that he observed. He thinks that the changes in the so-called sympathetic cell groups of the spinal cord and of the brain stem, which he observed in two of his patients, might be of especial interest since they present a proof for the hypothesis of the existence of a connection between the diencephalon and the visceral nucleus of the medulla oblongata. The impairment of these connecting tracts may elicit sympathetic disturbances in the same manner as a lesion of the sympathetic centers in the diencephalon and the medulla oblongata.

Acute Endocarditis and Endocarditis Lenta—Schwalbe stresses the differences between acute endocarditis caused by *Streptococcus viridans* and endocarditis lenta. Since former studies on this problem disclosed no difference in the type and the virulence of the various strains, it is necessary to find other factors that cause a fulminant course although the pathogenic organism is not highly virulent. The author thinks that the severe lesions of the heart and the congenital or acquired valvular lesions should be given first consideration. She admits that in some instances the defect may become so rapidly decompensated that death follows quickly as a result of it. However, in the majority of cases of acute endocarditis that is not the case. On the contrary, the severity of the infection usually causes the fatal outcome. On the other hand, superinfections may bring on a turn for the worse, such as pneumonia, meningitis, uremia or the existence of an old tuberculosis. Moreover the patient's general condition should not be disregarded. An undernourished body and one that has been exhausted by cares and excitement is hardly capable of mobilizing the necessary defense powers. To be sure this factor is probably rarely of significance in the case of a fulminant course. The author points out that her theories about the cause of acute endocarditis *viridans* are essentially the same as those expressed by Schottmüller. Since the cases in question form exceptions to the aspects of the typical picture of endocarditis, it is to be assumed that the virulent conditions have been shifted that is as a result of reduced defense power and impairment of the heart the organism is not equal to the increased requirements.

*Influence of Antirachitic Therapy on Electrocardiogram of Children
W. Uhse—p. 63

*Quantity of Blood During Collapse in Alimentary Intoxication of Nourlings
H. Seckel—p. 81

Studies on Psyche of Mongolian Idiots
Margret Kulenkampff—p. 87

Influence of Viosterol on Electrocardiogram—Uhse points out that, in addition to the therapeutic effects viosterol also exerts a toxic influence, and he substantiates this by reviewing the literature and by his own observations. In all, he examined eighty-two children. The first group of twenty-one children had been treated with a viosterol milk of which 0.5 liter contained approximately three drops of standardized viosterol in oil. In all these children the treatment had the desired antirachitic effect, but seventeen of them showed an abnormal electrocardiogram. A second group of sixteen children was treated with viosterol in oil, and all but one showed changes in the electrocardiogram. A third group of twenty children was given cod liver oil with viosterol, and disturbances in the electrocardiogram developed in fifteen. The fourth group of eight children was treated with pure cod liver oil, and seven developed electrocardiographic changes. The fifth group of seventeen children was subjected to quartz lamp irradiations, and these showed no changes in the electrocardiograms at the end of the treatment. The electrocardiographic changes that developed in the first four groups were nearly always in the final wave that is in the part that begins with S and ends after T. The question of whether there is a connection between the dosage of viosterol and the pathologic manifestations in the electrocardiogram is answered by the fact that in the author's cases the minimum doses were given and still the changes developed. The electrocardiographic changes that develop fol-

lowing medication with viosterol largely resemble those which develop after infections, such as scarlet fever myocarditis in which myocarditic foci are present. Thus it appears possible that medication with viosterol may lead to myocardial impairment. However, while most postinfectious electrocardiographic changes are only transitory, those caused by viosterol are still present from six to nine months later. It is worthy of note that the sensitivity to viosterol decreases with the age of the children. The author observed that nurslings and small children who are less than 2 years old are most likely to develop electrocardiographic changes following treatment with viosterol. Older children and adults are less exposed to this danger. Moreover, children with rickets tolerate viosterol better than those without rickets.

Alimentary Intoxication of Nurslings—Seckel shows that during alimentary intoxication of nurslings there develops a true circulatory collapse with reduction of the circulatory quantity of the blood. This decrease in the circulating amount of blood is due to inspissation as well as to storage in the depot organs. Both these factors lead to a retardation of the blood stream and to a reduction in the minute and beat volume of the heart. The smaller beat volume of the heart during collapse is indicated by a diminished size of the cardiac shadow in the roentgenogram and by the diminution or the complete disappearance of the first heart sound.

H. Buschbeck—p. 344

*Treatment of Suppurating Tumors of Adnexa
S. S. Barjaktarov—p. 352

Treatment of Myomas—Studies of 501 cases convinced Guthmann and Atzert that the results of surgical treatment and of ray therapy are approximately the same if the effect of the total roentgen menolipsization is compared with the total extirpation of the uterus, and if the effect of temporary menolipsization is compared with partial extirpation. The disturbances that develop as sequels of the treatment of myoma are about the same with the two methods of treatment. The symptoms of abolished function, for instance, appear with about the same frequency after total roentgen menolipsization as after total hysterectomy with the removal of both ovaries (in about 87 per cent of the cases). The preservation of one ovary produced a more favorable result, since the symptoms of abolished function appeared in only 63 per cent of these cases. But even in enucleation of the myomas, in which the genital function is not interfered with, symptoms of abolished function are present in 23.5 per cent of the cases. This indicates that the psychic factors play an important part. The increase in weight was about the same in all types of treatment, as regards the incidence as well as the degree of increase. Cohabitation was impeded by processes of involution in about 14 per cent of the cases after irradiation as well as after surgical treatment. These and other observations convinced the authors that the treatment of myoma should be individualized. In determining the best therapeutic methods the following factors should be considered: (1) the type of myoma (subserous, intramural, submucous, intraligamentary), (2) the complications, (3) the age of the woman, (4) the preservation of the menstruation and the conception capacity, (5) incretory disturbances and (6) nervous disturbances.

Treatment of Suppurating Tumors of Adnexa—Barjaktarov treats suppurating tumors of the adnexa in the following manner. After a thorough irrigation with antiseptic solutions, the vagina is dilated by écarteurs. The lower lip of the uterine cervix is grasped with a mouse tooth forceps and is drawn, horizontally and slightly upward, to the vaginal opening. In this manner, the posterior vaginal vault is completely exposed and easily accessible. Then the upper vaginal écarteur is removed and the posterior vaginal vault is iodized and dried. If the cervix is drawn forward horizontally, a bend is formed in the vaginal vault that corresponds to Douglas' pouch. The puncture is made in this bend. The needle should be parallel to the uterus. This is especially important, if only a portion of

the tumor has entered the Douglas pouch. After the needle has reached Douglas' cavity, it is directed toward the right or the left to reach the tumor. In the event that the tumor is located high up, an assistant has to exert pressure on the abdomen in order to press the tumor down into Douglas' pouch. After the tumor has been punctured with the needle, the pus is pumped out and 2 or 3 1,000 solution of ethoxydiminoacridine lactate is introduced and then withdrawn again. The quantity of the solution should be the same as that of the pus which has been removed. The solution is introduced and removed several times until it returns clear. As a rule the third irrigation yields clear fluid. The author employed this method in 137 cases of suppurating tumors of the adnexa. In the majority of cases, complete cure was effected, in the others, improvement was obtained.

Modified Takata Reaction in Liver Disease Lilly Rappolt —p 253
Simple Ulcer of Cecum W Thaler —p 255
Hypersensitivity of Skin to Balsam of Peru W Engelhardt —p 256

Takata Reaction in Liver Diseases—In reviewing the history of the Takata reaction, Rappolt points out that Jezler and Staub employed it first on the serum of patients with hepatic disturbances. She describes the results obtained with the test on 348 patients with suspected hepatic disorders. Of the patients in whom cirrhosis of the liver was certain, 85 per cent had a positive Takata reaction. In patients with chronic alcoholism and cirrhosis, however, the reaction was usually negative. In icterus and other hepatic disorders 20 per cent gave a positive flocculation reaction, and in all these a considerable damage of the liver could be suspected. Of the patients with various other disturbances, 37 per cent had a positive Takata reaction and approximately 75 per cent of these positive cases showed a decompensated circulatory disorder with stasis of the liver. The positive Takata reaction was always accompanied by an increase in the seroglobulin but there was no absolute parallelism between the outcome of the Takata reaction and the degree of the globulin increase and the sedimentation speed of the erythrocytes. The author concludes that the Takata reaction is a valuable diagnostic aid in differentiating a cirrhosis of the liver from other hepatic disorders.

Simple Ulcer of Cecum Simulating Appendicitis—Thaler gives the history of a woman aged 38 who complained of symptoms indicative of appendicitis. The operation revealed that the appendix was normal, but inspection of the cecum disclosed a simple ulcer the size of a hen's egg. An ileocecal resection was done and the postoperative course was at first uneventful, but later peritonitis developed and the woman died. A review of the literature disclosed that a high percentage of patients with cecal ulcer die of perforation peritonitis. The author's aim in reporting this case was to call attention to the fact that cecal ulcers often simulate appendicitis and to stress that when the appendix is found normal, the colon should be carefully inspected for the presence of ulcer.

Hypersensitivity of Skin to Balsam of Peru—Engelhardt states that hypersensitivity of the skin to balsam of Peru is present in 2 per cent of persons who have no skin disease and have never used ointments. In patients with skin disease who have used ointments much, hypersensitivity exists in 10 per cent. The hypersensitivity to balsam of Peru is monovalent that is, tests disclosed no polyvalent sensitization to other eczematous substances and no nonspecific irritability of the skin. All constituents of balsam of Peru are involved in the sensitization, for they all produce positive hypersensitivity reactions. In view of the high sensitizing power of balsam of Peru it is inadvisable to treat large wound surfaces including chronic eczemas, for long periods with balsam of Peru. At any rate the patch test (Jadassohn-Bloch) should be made whenever extensive application of a preparation containing balsam of Peru is intended.

Transfusion of Serum for Control of Bleeding—In the modern conception of the therapeutic effect of blood transfusion the principal role, according to Filatov and Kartasevskij, is assigned to the introduction of living erythrocytes in the blood of the recipient, while that of the blood serum has been but little investigated. The authors studied the effect of blood serum transfusion as well as the question of conservation of the serum for the last one and one-half years. The blood of the donor was received in a flask half filled with a preservative (sodium citrate 5, sodium chloride 9, distilled water 1,000). The mixture was kept from three to four days in the icebox and the supernatant serum siphoned off and placed in sterile flasks having a capacity of from 50 to 250 cc. Serum transfusion was practiced in seventy-two cases. The authors conclude that the hemostatic effect of serum transfusion equals that of whole blood transfusion. The serum may be preserved for months though the exact limit has not been determined. Smaller quantities (from 50 to 150 cc) of serum are adequate for hemostatic purposes. Because it does not contain agglutinins, the serum from groups A and B may be given any patient without determining his blood group. Further study is required to determine the question of applicability of serum transfusion for the purpose of replacement as well as for its efficiency in manifesting the immunobiologic properties of whole blood transfusion.

- *Morphologic Manifestations of Allergic Reactions in Man A I Abrikosov —p 619
*Differential Diagnosis of Spasm and of Occlusion of Coronary Arteries L I Fogelson L F Limcher and M G Traynias —p 736
*Rational Classification of Rheumatic Disorders L B Bukhshtab —p 765
*Dyskinesia of Biliary Tracts E S Shakhbazyan —p 964

Morphologic Manifestations of Allergic Reactions—Abrikosov states that morphologic manifestations of allergic reactions are of two types (1) new and peculiar alterations in a tissue that hitherto has presented nothing abnormal and (2) alteration of the type of previously existing inflammation. The peculiar alterations in a previously normal tissue are of the nature of hyperergy, best characterized as alterations of the type of Arthus's phenomenon. Here belong changes of the mesenchymal tissue in acute rheumatism, changes of the wall of the vessels in malignant nephrosclerosis, nodous periarteritis and obliterating thromboangitis (Bürger). The hyperergic alterations of the walls of the blood vessels seen in various infectious diseases likewise belong here. The essential feature in all is a peculiar necrobiotic disorganization of the mesenchyma in the form of an initial "fibrinoid swelling" of tissues with consequent inflammatory manifestations and sclerosis. The change in the character of the inflammatory reaction in hyperergy manifests itself in a rapid course and a disproportion to the causative factor. The morphologic changes observed are those of exudation, hemorrhagic manifestations and, not infrequently, circulatory disturbances in the form of stasis. A chronic mild inflammatory process with a predominance of proliferation and a tendency to fibrosis characterizes the anergic reaction. The author calls attention to the fact that a number of allergic reactions manifest themselves in functional rather than morphologic reactions as for example, the muscular spasm of bronchi in asthma or the pylorospasm. On the other hand certain allergic reactions present ordinary alterations without any specific character such as the manifestations of serum disease, of rhinitis in hay fever, of the alimentary idiosyncrasies and of eczema.

Diagnosis of Occlusion of Coronary Arteries—Fogelson and his co-workers state that the clinical picture of an attack of angina pectoris does not enable one to diagnose a coronary occlusion in many instances. This question can be

decided, however, by an electrocardiogram. Sclerosis of the coronaries is not necessarily accompanied by spasmodic phenomena. A vascular spasm in the presence of normal nerve plexuses of the adventitia need not cause painful sensations in every instance. Consequently, a coronary occlusion may take place without causing painful sensations and be recognized only in the electrocardiogram. The changes in the electrocardiogram enable one to estimate the magnitude of the involved cardiac segment. The rapidity of return to normal judged from protracted electrocardiographic observations is an indication of the size of the newly formed scar and the establishment of collateral circulation. If the electrocardiogram fails to return to normal, the involved segment is large and has been replaced by a scar. On the other hand, a rapid return to normal indicates that the involved segment of the myocardium is not large, that the sclerotic process in the coronaries is not extensive and that a collateral circulation has been reestablished. The authors conclude that a spasm of the coronary vessels constitutes the cause of an anginal attack and that the spasm may lead to their occlusion. The latter is observed in the majority of instances of sclerosed coronaries. The clinical picture is not always sufficient to enable one to diagnose thrombosis. Severe anginal attacks may pass without coronary occlusion taking place, and on the other hand coronary thrombosis may fail to give rise to a painful syndrome. The determining factor in the differential diagnosis between a spasm and occlusion is the electrocardiogram. Systematic electrocardiographic observations make it possible to estimate the magnitude of the myocardial segment involved, as well as the rapidity of the resolution of the myelomalacic focus.

Classification of Rheumatic Disorders—Bukhshtab proposes the term "true rheumatism" for a clinical entity the etiology of which has not been completely elucidated but which presents lesions of the connective tissues, particularly of the heart. This lesion is a granulomatous process described by Aschoff and considered an expression of a particular hyperergic condition of the organism. The heart is always affected and therefore constitutes a specific primary factor. The polyarthritides are a secondary factor and, while usually present may be absent. These truly rheumatic acute polyarthritides seldom pass into a chronic stage. The invalidism that ensues is always cardiac in nature. The clinical characteristic of this disease, according to the author, is a biologic reaction to cooling. The reaction consists in lowering of the leukocyte count when a joint is exposed to the cooling effect of ether. This occurs only in the blood of a "true rheumatic patient" and is absent in other forms of so-called rheumatism. The correctness and constancy of the reaction have been confirmed by observations of various authors on some 500 patients. This reaction enables one to recognize rheumatism in its vascular form, in the absence of joint involvement.

Dyskinesia of Biliary Tracts—Shakhbazyan states that the diagnosis of dyskinesia of the biliary tracts is difficult. Its recognition is possible only through elimination of other diseases of the biliary tract and of the adjacent abdominal viscera, such as the pancreas, the stomach, the duodenum and the right kidney. The most important clinical methods of investigation are duodenal drainage and cholecystography (normal B bile and normal gallbladder shadow). The average of wrong diagnoses is at least 50 per cent. Surgical therapy for the so-called dyskinetic disturbances of the biliary tracts is poorly founded. The late results of the various procedures, such as cholecystectomy, choledochoduodenostomy or stretching of the sphincter of Oddi, give poor results. The internal medical treatment, as a rule, brings about the desired results.

 Investigations on Iron Metabolism in Pregnancy. 1. Iron Content of Our Food. K. U. Toverud—p 177
 Oldest Description of Bubonic Plague. B Ebbell—p 185

Cancer in So-Called Atheromas—Hval reports one case of papilloma developed in a retention atheroma and twelve cases in which the atheroma developed into carcinoma. Of the twelve, ten were in women and two in men, all but two of the patients were more than 50 years of age. In ten cases there was squamous epithelial cancer with canceroid pearly formation, one instance with papillomatous structure being regarded as a probable transition form. Relatively marked inflammation was seen in these cases. In two cases the tumor was of certain papillomatous nature, in one there was mucous degeneration, and in both the cell form resembled that in basal cell carcinoma of the skin. The author says that the malignant development occurs in cysts that have been of unchanged size for many years, seems to be slow in all cases, and is relatively benign. Beginning growth of the cysts, suppuration or beginning pain have led to their removal. On excision of painful or suppurating atheromas in older persons the possibility of carcinomatous degeneration should be borne in mind.

Sarcoma with Unusual Localization—The first case of polymorphic cell sarcoma of the penis in a man aged 63 is attributed to trauma at the site one year earlier. One of the two cases of subungual sarcoma was in a girl of 15, the other in a woodchopper aged 40. Hval says that both cases presented a characteristic history with unusually pronounced pain in the finger after the lapse of months a not particularly characteristic ulceration appeared. In long-continued onychias the possibility of sarcoma should be considered and histologic examination of a specimen excision made. Treatment must be radical, and favorable results depend largely on early diagnosis.

Total Gastrectomy for Cancer—In Bull and Stang's case, with large cancer along the upper part of the major curvature up to the cardia, total gastrectomy with retrocolic esophagojejunostomy and jejunoejejunostomy was performed in February 1933. The patient was a man, aged 40, in good general condition, there were no large glandular metastases and the intra-abdominal portion of the esophagus was free from cancer and long enough to make it unnecessary to loosen the esophagus from the hiatus in the diaphragm. After-examination in March 1934 revealed that he had been in full work as a railroad machinist since August 1933 and had gained 7 Kg. He takes from 0.5 to 0.75 Kg of liver weekly. There was a slight anemia with an almost normal blood picture. Absorption tests showed a protein loss of 32 per cent, a fat loss of 30.14 per cent and a carbohydrate loss of 1 per cent, the loss of protein and of fat being slightly higher than in normal persons.

PERIPHERAL VASCULAR DISEASE

ITS SIGNIFICANCE FOR GENERAL PRACTITIONERS
AND SPECIALISTS

GÉZA DE TAKÁTS M.D.
CHICAGO

It is no exaggeration to say that thousands of individuals are unconscious or mildly conscious of a progressive interference with their peripheral circulation. Their feet may be pulseless but still in a stage of compensation. Their margin of safety is minimal. Their "rheumatic" pains come and go with changes of weather, mechanical stress or emotional load. An occasional numbness or tingling of the extremities is disregarded. They undergo an annual or semiannual physical examination during which peripheral circulation is ignored, although the heart is carefully examined, chest plates are taken and electrocardiograms are read. Insurance examinations may be made or physical examinations when they apply for a new job, but nobody palpates the pedal pulses.

As a result, the middle aged wage earner, the insured policyholder, or the railroad or street car conductor suddenly develops a serious interference with the peripheral blood flow. Did this really come out of a clear sky? In most instances this was surely not the case. The lesion had existed for a considerable time and was probably caused by a sudden aggravation of a chronic progressive arterial obstruction.

Who sees these patients first? Undoubtedly the general practitioner. Many cases of peripheral vascular disease are also encountered by internists, orthopedic surgeons, traumatic and industrial surgeons, neurologists and dermatologists, whose special field of interest lies somewhat apart from problems of peripheral circulation.

In the maze of newer, often conflicting, data the study of peripheral circulation has been confined so far to a few peripheral circulatory clinics, where facilities are available for special study and therapeutic research. What is to happen meanwhile to the mass of people scattered among the practices of the general practitioner and many of the specialties?

The study of peripheral circulation has advanced to a point at which a simple office procedure can be included in the course of a thorough physical examination. It is my purpose in this paper to outline such methods of examination, evaluate their meaning and indicate the therapy of the most common peripheral circulatory disturbances.

METHODS OF EXAMINATION

The Peripheral Pulse—Very seldom is anything else but the radial pulse palpated. In most individuals the palpation of the dorsalis pedis, posterior tibial, popliteal and femoral arteries offers no difficulty. It must be remembered that in 4 per cent of cases the dorsalis pedis pulse is absent and that in another 8 per cent the artery is in a lateral position from the customary site.¹

Absence of pedal pulses is not infrequently found in older male patients who have no complaints. Their feet are warm and of good color, the slow gradual occlusion of the main vessels has permitted the development of an adequate collateral circulation. An absence of a palpable pulse wave furthermore is not an absolute indication that the vessel is completely obstructed. When the wall is rigid an even trickling of blood may still occur through the pulseless artery. Some arteries may pulsate at times and not at others, indicating a spastic element.

The Skin Temperature—The skin temperature of a given extremity depends on temperature and humidity of the examining room and body temperature. Should these factors be fairly controlled, in that the examination is made in a room around 22 C (70 F), with the patient resting, and normal mouth temperature, the skin temperature is then dependent chiefly on blood flow. Should this be diminished, the skin temperature will drop. Excessive perspiration, a sign of increased sympathetic stimulation, lowers the temperature by loss of heat. A dry skin, such as occurs after sympathectomies, will give a feeling of warmth but also measurably higher values of temperature. Skin temperatures can be estimated by the palm of the hand or finger tips, and differences larger than 0.5 degree centigrade are easily discernible. A mercury skin thermometer is handy and inexpensive. For practical purposes it substitutes well for the complicated and expensive electrical thermometers.

The value of skin temperature readings is limited to

- 1 Sudden drop in temperature of one extremity as a sign of inadequate arterial inflow
- 2 Marked differences between symmetrical areas on two extremities
- 3 A rise in temperature after various diagnostic measures that aim to relieve vessel spasm and thus determine the spastic element in the vascular occlusion

Certain it is that an elaborate battery of wires and galvanometers in rooms with constant temperature and humidity should not intimidate the general practitioner to use his head and fingers. The information obtained will be equally useful.

¹ Reich, R. S. Pulses of the Foot. Their Value in Diagnosis of Peripheral Vascular Disease. Ann. Surg. 99: 613-622 (April) 1934.

Postural Changes of Color—Pallor on elevation, which can be accentuated by rapid dorsal and plantar flexion,² and rubor in the dependent position are signs of diminished blood flow. At a certain level, which is usually below the horizontal position, the pallor changes into the normal color of the skin without showing the reddish hue of capillary stagnation. This is the optimal position for the patient. Mont Reid³ has strongly deprecated the senseless habit of elevating the legs of patients who are suffering from obliterative arterial disease. The elevated position only accentuates the difficulty of arterial inflow. Many patients have discovered that they rest much better when the foot is from 20 to 30 degrees below heart level and this optimal position should be determined for every patient. A dependent rubor is often seen in older patients and is not, in itself, an alarming symptom.

*The Cutaneous Histamine Reaction*⁴—For a long time methods of producing a reactive hyperemia have been used to demonstrate the extent of collateral circulation. Of these, the simplest and most definite is the intradermal injection of histamine, a powerful vasodilator. The acid phosphate salt of histamine in a 1:1,000 solution is obtainable in ampules. When 0.1 cc is injected intradermally within five minutes a characteristic flare is produced, with a wheal in the center. This flare is absent when (1) there is not enough head pressure in the skin vessels to fill up the arterioles dilated by histamine, (2) when an arterial spasm exists, which the histamine is unable to overcome, or (3) when the sensory nerves of the skin have degenerated, following peripheral nerve injury. The cutaneous histamine reaction gives the following information in patients with manifest or suspected vascular disease.

1. In patients with frank gangrene the lowest level of safe amputation is determined. When histamine wheals are placed at various levels of the extremity, avoiding bony prominences where the skin is under tension, the lowest level at which a normal histamine flare can be detected may be used as a site of a circular amputation. Circulation of the bone is usually affected at a skin level with normal response, for which allowances have to be made.

2. During a course of conservative treatment with drugs and physical measures, the improvement of the collateral circulation can be visualized.

*Blood Pressure Measurements*⁵—It is astonishing how little use is made of the ordinary blood pressure apparatus in the study of peripheral vascular disease, and yet a great deal of information can be gained, particularly if the dial type is used. The cuff can be placed above the ankle and above the knee. Differences of blood pressure on the two sides are significant. The level of systolic and diastolic pressures may be determined by palpation, by auscultation, or simply by watching the incoming pulse waves by the oscillations of the needle. In such determinations the patient should be in a horizontal position, possibly relaxed. In the sitting or standing position these pressures are much higher.

Far more satisfactory than an ordinary blood pressure apparatus is the oscillogram, which was especially constructed for this purpose. The data derived from this apparatus will inform the investigator about the level of the vascular obstruction, the intensity of myocardial contractions and the elasticity of the vessel wall, but it will not register the extent of collateral circulation, much of which does not pulsate. The oscillogram is not necessary for making a diagnosis, but it is invaluable for a thorough vascular study.

Reflex Dilatation to Heat—Peripheral vascular obstruction usually consists of two components (1) organic stenosis or obliteration of an arterial segment and (2) a vessel spasm, which is not permanent and which may be relieved by various measures. While there are pure examples of both types, such as a terminal stage of senile gangrene and Raynaud's disease, one is mostly confronted by a mixture of these two forms. There have been a number of measures suggested to differentiate vascular occlusions, such as induction of artificial fever,⁶ procaine hydrochloride block of peripheral nerves,⁷ or paravertebral ganglions⁸ and spinal anesthesia. None of them could be well applied by the general practitioner. The recently described test of Landis and Gibbon,⁹ however, gives adequate information as to how much dilatation the vascular bed is capable of producing, when central vasoconstriction is abolished. The examination should be made in a room preferably not warmer than 22°C (70°F). The temperature of the big toe is determined with a skin thermometer, for which even an ordinary fever thermometer can be used. Then the hands and arms of the patient are immersed in hot water (about 45°C or 113°F) for twenty minutes. This produces a reflex vasodilatation on the lower extremities. The rise in temperature, measured on the big toe, is the index of the amount of vasoconstriction that the reflex heat overcomes. When the normal vasodilatation level of 33°C (91.4°F)¹⁰ is obtained, the test has demonstrated a sufficient vascular bed to overcome the organic obstruction. However, as frequently occurs in older, arteriosclerotic individuals should the rise in temperature not be sufficient to reach the normal vasodilatation level, one must assume a deficiency of the available collaterals, a diminution of safety factors. This test then not only reveals the element of spasm in a given patient but has prognostic value, as it measures available collaterals.

Other Methods of Examination—The aforementioned procedures can be readily carried out without any special equipment. They permit of a fairly accurate estimation of the patient's peripheral vascular status. There are naturally special methods of examination, such as roentgen examination for calcified vessels, blood vessel visualization after the injection of opaque substances into the arteries, biopsies of vessels, determinations of blood volume or blood viscosity, the plethysmograph,¹⁰ and exploration of other vessels in the body by electrocardiogram and ophthalmoscope.

some of which are employed in certain cases and are not part of the simple routine just outlined. With the palpation of pulses, the estimation of skin temperature, observation of postural color changes, the determination of the histamine reaction and, finally, study of blood pressure and reflex vasodilatation the general practitioner can form a well grounded opinion about the peripheral vascular status of the patient.

PRINCIPLES OF DIAGNOSIS AND MANAGEMENT

The object of management in peripheral vascular disease naturally depends on the character of the lesion. Having divided these lesions into organic and functional, I shall briefly discuss the leading principles in the management of these disorders.

Organic Lesions—Flow of arterial blood to the periphery may be interfered with by congenital anomalies, which mostly take the form of multiple arterio-venous fistulas.¹¹ Their cure is essentially surgical. An early attack on the anomalous communications, provided they are susceptible of approach, gives excellent results.

Traumatic lesions of arteries produce thrombosis, expulsive hemorrhage or aneurysm. Their management is purely surgical and is not within the scope of this article. It must be emphasized however, that many of the previously dreaded, formidable procedures have become safe or limb saving operations. The preoperative estimation of collateral reserve, the improved surgical technique and the measures that are now known to increase the vascular bed in times of stress have produced gratifying results. The early recognition of a peripheral embolism and its surgical relief within the first sixteen hours is one of the latest triumphs of medical progress.¹²

Other nonmechanical injuries of arteries, caused by cold, heat, lead or arsenic, radium, x-rays and electricity, always produce the same reaction in the vessel wall, namely, a proliferation of the intima, subintimal cushions of granulation tissue, stenosis and finally thrombosis of the artery. From a prognostic point of view it is important to know that the extent of initial injury can hardly permit an estimate of the final damage to circulation. Thus a simple frost bite manifestly involving one or two toes may gradually lead to an endo-arteritis at a much higher level, and this is true of all other forms of injury.

The treatment of all such injuries is highly conservative. The vessel spasm that appears as a direct or reflex stimulation of the arterial musculature seems to be best relieved by large doses (from 40 to 60 grains, or 2.6 to 4 Gm.) of theobromine sodium acetate.¹³ Papaverine by mouth or even intravenously also relieves vessel spasms and may tide the patient over a critical period in incomplete peripheral or pulmonary embolism.¹⁴ Collateral circulation is encouraged by continuous heat produced by an electrical baker. The temperature in the baker should be around 85 to 98 F. never above 100 F.¹⁵ The use of intermittent negative pressure to suck in more blood and hasten the formation of collateral circulation has been proposed by

Landis and Gibbon¹⁶ and by Herrmann and Reid.¹⁷ This method, used in the properly selected case with certain precautions, seems an effective principle of developing adequate collaterals.

In the acute and subacute forms of vascular injury, active postural exercises, as described by Buerger, are not advocated. They may aggravate pain and are not in keeping with the important principle of rest for such an extremity. I feel the same way about the alternate hot and cold baths. Their proper place will be discussed later.

Infections The majority of authors feel that Buerger's disease (thrombo-angitis obliterans) is an infectious disease of unknown etiology.¹⁸ Certain it is that a number of known specific infections such as syphilis, tuberculosis, typhoid and paratyphoid, streptococcal infections in the presence of bacterial endocarditis, scarlet fever, general septicemia and rheumatic infections may affect the peripheral arterial tree probably more often than is suspected. The role of ergot in producing vascular occlusions has also been reemphasized.¹⁹ Evidence of specific infections elsewhere in the body together with the aid of biopsies of smaller vessels may help to differentiate a group of infections from Buerger's disease. In fact, there may be a time when true Buerger's disease will become more and more infrequent, because many of the cases diagnosed at present as Buerger's disease will be differentiated into vascular infections of known etiology. The recovery of the offending organism permits the use of autogenous vaccines, which is the rational therapy.

So long as the causative organism in Buerger's disease is unknown, the use of nonspecific vaccines offers the best line of therapy. It is not sufficiently emphasized that a nonspecific vaccine may desensitize a patient to another specific organism.²⁰ There is some clinical evidence that in Buerger's disease the vascular endothelium is abnormally vulnerable to injury. Thus a slight sore throat, an infection of the upper respiratory tract, or a slight trauma may aggravate or light up a quiescent process. An ardent advocate of hypertonic salt solutions in the therapy of Buerger's disease has observed venous thrombosis after the use of 5 per cent solutions of sodium chloride.²¹ The therapy of Buerger's disease, to my mind, is primarily an effort to desensitize the patient to an unknown agent or agents. The patient may be sensitive to tobacco,²² but this is probably only a part of the abnormal vulnerability to vascular insults, some of which are bacterial.

The administration of triple typhoid vaccine, strongly advocated in the therapy of Buerger's disease, has been the method of choice in my clinic. However, I do not believe that the creation of intense reactions, chills and fever is important. On the contrary, such reactions during the chills have been known to lead although very rarely, to thrombosis.²³ It has been my custom to

start with as little as 1,000,000 bacteria intravenously and, should this produce a febrile reaction or malaise, to reduce the dose to 100,000. Exactly as in the therapy of rheumatic disease,²⁴ the minimal dose producing a favorable local response without a general reaction is the optimal dose. When such a dose is once determined, it is repeated until no relief of symptoms is obtained. At this time an increase in the dose is advisable, but never one that will produce a high temperature with chills. The vaccine therapy requires considerable skill and experience. When not properly handled, it may aggravate the patient's condition.

Because of the increased viscosity of the blood, which has been demonstrated in these patients, a sufficient water intake of from 3 to 4 quarts of water should be maintained. When this water contains some salt in the form of Ringer's solution or separately 10 Gm of table salt to every quart of water is consumed during the day, the water will be much better retained than if it is taken without salt.²⁵ I do not specially advocate, however, large doses of salt solution intravenously, as venous thrombosis frequently occurs.

Smoking is absolutely prohibited, it produces or aggravates vessel spasm.²⁶ Denicotinized tobacco tastes so bad that it serves as an excellent transition to complete abstinence. Alcohol on the other hand, if the patient is used to it, is not harmful when moderately used. Its peripheral vasodilator effect is common knowledge. It is doubtful, however, whether its use as an analgesic in the excruciating pain of vessel obstruction should be encouraged. These patients may become chronic alcohol addicts and will require and request more and more for the relief of pain.

Nor should morphine be given if its use can possibly be avoided. Should the pain be due to ischemia vasodilators, such as theobromine, and continuous heat are most helpful. If the pain is due to a peripheral neuritis, which may accompany inflammatory or degenerative vascular lesions, a combination of 5 grains (0.3 Gm) of amydopyrine and one-half grain (0.03 Gm) of phenobarbital is of benefit. The desensitization of the foot by injections of alcohol²⁷ or section and immediate suture of the sensory nerves of the foot²⁸ is not a harmless procedure. It deprives the foot of important defense mechanisms such as pain on injury and reactive hyperemia in infection. In my limited experience with these methods, the immediate result was a dramatic relief from pain, the late result was an amputation. The removal of infected foci is well worth while, not with the idea that the process in the vessel wall will be influenced but to prevent further flare ups, further sensitizations.

Sympathectomy in Buerger's disease has been debated pro and con. The difficulty of evaluating the effect of sympathectomies in this disease lies in the fact that (1) the etiology of Buerger's disease is unknown and its general vascular distribution is variable, and (2) the effect of sympathectomies on the peripheral vascular bed is far from being clear. The following

considerations have influenced me against performing sympathectomies in true Buerger's disease.

1 It is a generalized vascular infection, involving not only peripheral vessels but any other vessel, coronary, renal, cerebral or mesenteric. 2 The extremity uninvolved at the time of sympathectomy is not protected from extension and progress of the vascular occlusion at a later time.²⁹ 3 The end results are not strikingly different from those obtained by conservative measures.¹⁸ It must be emphasized, however, that a group of vascular diseases which exhibit vessel spasm and are due to chronic endo-arteritic processes respond very well to sympathectomy. This is the group that Mont Reid designates as endarteritis obliterans.³⁰ Unfortunately, the medical profession at large has not made any distinctions in the past between Buerger's disease and endarteritis obliterans. In fact, these two conditions are frequently used as synonyms.

Buerger's disease (thrombo-angitis obliterans) is a progressive vascular inflammation attacking chiefly young males who are not necessarily Jews or smokers. There is a characteristic history of spontaneous phlebitis or cutaneous nodules resembling rheumatic nodules, a slow but steady or intermittently exacerbating progress of the disease that involves many arterial segments. In analogy of the typical syndrome of migrating phlebitis, this disease is a migrating arteritis, with secondary thrombosis and recanalization.

This should be contrasted with the occlusion of a single vessel or vascular tree, which may be due to any one of the traumatic or infectious processes already enumerated. There is no history of phlebitis or cutaneous nodules, no evidence of progression, and no change in blood viscosity or blood volume. Such a patient has a healed scar in place of a normal artery. Should this maintain a reflector vessel spasm, sympathectomy will relieve it.
